Quantum jumps in the yield potential of crop plants generally resulted from the modification of plant types. New plant architecture permitted the yield potential of rice to be doubled in the mid-1960s, which was characterized by short stature, high tillering, sturdy stems, and dark green, erect leaves that were largely contributed by DGWG or its derivatives and the tropical indicas. To make another quantum jump in the yield potential, modification of the present high-yielding plant type has been explored. The prototype is described as short stature (90–100 cm), low tillering (6–10 tillers under transplanting, no nonproductive tiller), dark green, and erect leaves. These new plant types are likely to have 20% higher yield potential than the highest currently cultivated. Heterosis between indica/japonica crosses is regarded as the most feasible way to achieve such a breakthrough.

Exploitation of Heterosis

An F_1 hybrid of two genetically dissimilar parents showing increased vigor at least over the mid-parent value (the average performance of two parents) is known as heterotic (shown heterosis). The use of F_1 hybrids in commercial production hinges on the extent of heterosis, and the ease and costs of F_1 seed production. Since the early 1970s, a massive program of hybrid rice breeding has been operated in China, and recently in other rice-producing countries. Currently, more than half the rice area is planted to breed hybrid rice in China. The hybrid rice were described as having a vigorous root system, vegetative growth vigor, high tillering ability, large and dense panicles, heavy grains, and wide adaptiveness. Hybrid rice in China is mainly based on a cytoplasmic male sterility (CMS), which originated from a wild rice plant from Hainan Island, and fertility restoration system. Hundreds of CMS lines have been bred in China for hybrid rice production. These CMS lines could not be directly used as such to develop rice hybrids for the tropics because of their susceptibility to diseases and insects, and poor adaptability to tropical climates. New CMS lines were bred at IRRI and by various national programs using the wild abortive (WA) CMS system from China. New sources of CMS have also been identified at IRRI. There is no dearth of restorers among the elite indica rice germplasm in the tropics and subtropics, but the degree of restoration varies greatly and is sometime subject to environmental stresses, such as high temperature.

Use of photoperiod-sensitive/thermo-sensitive genic male sterility (P/TGMS) has been extensively studied during the 1990s in China and elsewhere. P/TGMS line is used both for seed multiplication, which is done by a cross between a CMS line and its responding maintainer line in CMS system, and hybrid seed production, thus greatly simplifying seed production, because there is no need for maintainer lines. Hybrid rice facilitated by P/TGMS is named as two-line hybrid rice, and that facilitated by CMS as three-line hybrid rice. Several sources of TGMS and PGMS have been reported in China and other countries such as in Japan and the United States. In the two-line hybrid rice system, most conventional varieties are natural restorers for P/TGMS lines; thus, there is greater flexibility in selection of restorer line, and the fertility of hybrid plants is more stable than in the three-line system. Theoretically, two-line hybrids have more chance to gain greater heterosis, because there is less restriction on the choice of parents in comparison to the CMS system. However, because almost all indica two lines tend to be thermo-sensitive, and it is almost impractical to find a place where the temperature is absolutely stably higher than a certain degree because of raining and storms across different years, therefore, the seed production of the two-line hybrid rice has more restrictions than that of the three-line hybrid rice, which makes it inapplicable to many areas.

The genetic basis of heterosis is quite complicated, but it depends, in a large part, upon the genetic diversity between the two parents. The greater the genetic difference in the parents, the higher the potential heterosis. Since the 1970s, the genetic diversity among improved indica rice has narrowed due to massive international exchange of germplasm. Indica and japonica germplasm have, however, remained distinct, as there has been relatively very little gene flow between these two subspecies. As expected, the inter-subspecies hybrids showed greater heterosis for yield than did indica/indica hybrids. The new plant-type development program based on tropical japonica germplasm would also be utilized for producing hybrids with better heterosis. Successful instances are development of superyield rice varieties “Liang-you-pei-jiu (Pai’ai 64S/9311)” and “Xie-qing-zao A/T9308” with the highest yield potential of 12 t ha^{-1} in China.

Breeding Methods

Development of new rice varieties always starts with the selection of parental varieties, no matter what kind of breeding method to be used. It consists of several important steps in rice breeding: the first is the creation of variation, the second is selection and obtains homozygous promising lines, the third is yield, quality, and other agronomic performance on plot basis, and finally participating official regional and national yield trials and registration of new varieties (Figure 1). Depending on the method of variation creation and homozygous line production, there are several methods in rice breeding (Figure 2).

Cross-Breeding

Genetic diversity among plants in a population is a prerequisite for successful plant breeding. Natural genetic variation has been used as a raw material in rice breeding. Hybridization has long been used to enhance genetic variability or to synthesize varieties combining desirable characters from two or more parents. The pedigree method of selection has been the predominant practice of rice breeders in handling segregating generations from the F_3 and beyond. The bulk method is particularly valuable where quantitative characters are concerned, such as yield of grain. It has the great potential advantage of reducing work in the early generations, as well as the demands on field space, so enabling the breeder to handle a larger number of crosses.

The backcrossing method may be expedient when a breeder wishes to make specific and limited improvement on a well-adapted and preferred variety. Backcrossing consists essentially of recurrent crossings to the hybrid progeny with one of the original parents (recurrent parent) with the objective of perpetuating a particular character possessed by the

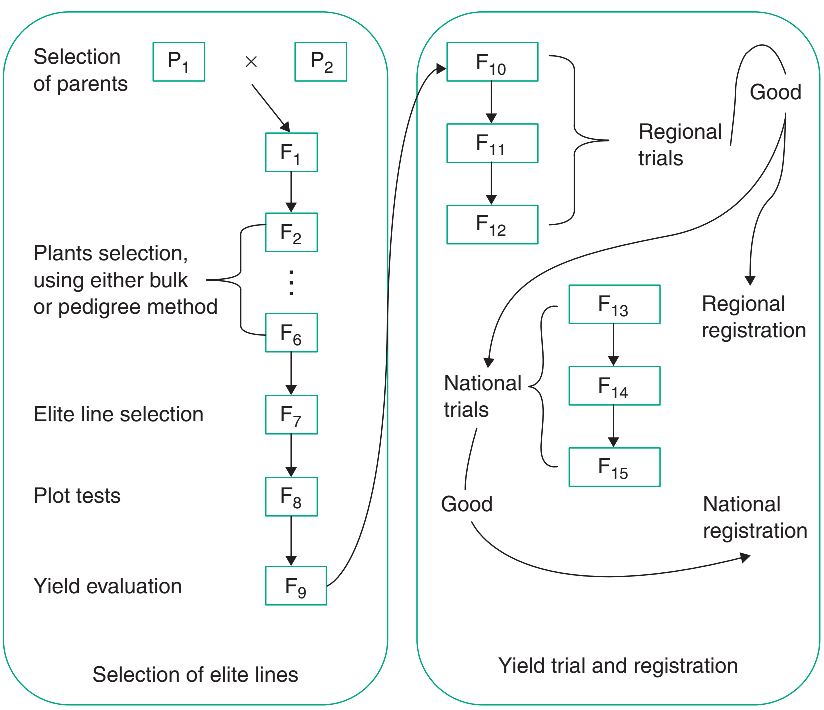

Figure 1 Flowchart of rice breeding and new variety registration.

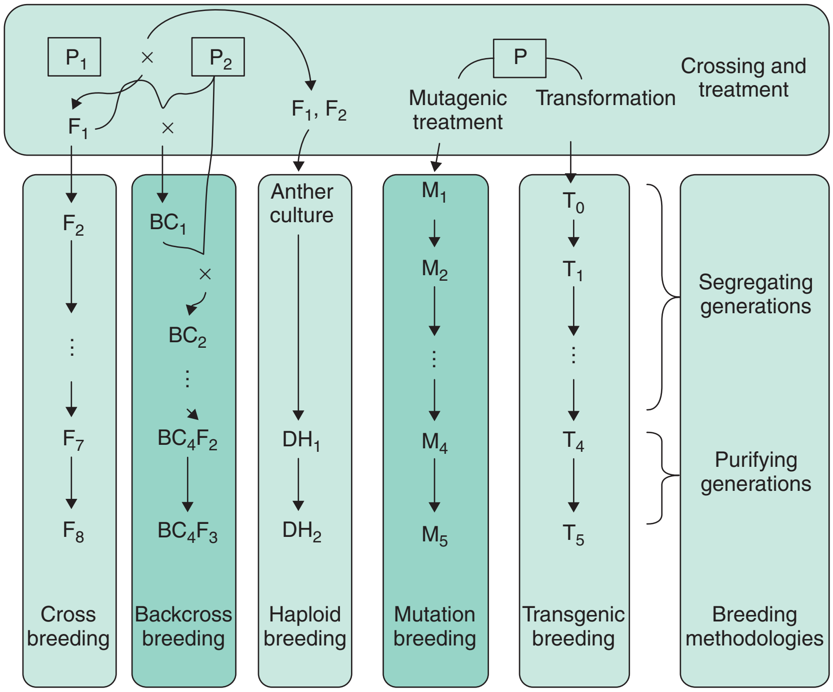

Figure 2 Flow chart of various methodologies for rice breeding.

donor parent. Backcrossing is particularly useful in increasing resistance to particular diseases. Recurrent selection following intercrossing could be helpful in improving traits that are under polygenic control and have low heritability.

Induced Mutation

Normally, the spontaneous mutation rate in rice is very low. The use of induced mutations has become a routine tool in rice breeding where convenient sources of radiation and chemical mutagens are available. Large number of mutants have been produced, most of which were by gamma irradiation of dried seeds. Chemical mutagens, mainly alkylating agents such as *N*-methyl-*N*-nitrosourea (MNH) and ethylmethanesulfonate (EMS), have been tested for their usefulness in mutation induction, but seldom used in practical breeding programs. A combination of chemical mutagens and radiation was applied in some cases. Semidwarf and early maturity are the characters most frequently achieved in released rice mutant varieties. Among other widely used mutated characters are those for grain quality, blast tolerance, salinity tolerance, and photoperiod insensitivity. Artificially induced mutations are very often accompanied by deleterious recessive genes, and even with chromosome damage leading to sterility. Therefore, mutants are also often used in cross-breeding as parents, which is known as indirect use of mutants.

Worldwide, numerous rice varieties have been developed by using induced mutations, and many of them have (had) been commercially planted. Zhefu 802, an indica variety developed by gamma irradiation, might be the most extensively grown mutant rice variety. Its accumulative planting area reached more than 12 Mha during 1986–94 in China. The semidwarf mutant variety Calrose 76, also induced by gamma rays irradiation from Calrose in California, USA, on the other hand, has been the semidwarf gene (sd1) donor of most modern American rice varieties, and of rice varieties grown in Australia recently. Induced mutations could be more readily used in crosses than exotic source when a desired trait could not be found in the local group of varieties. Meanwhile, mutagenic treatment could also serve as a powerful tool in breaking down the tight linkage and thus increasing recombination frequency in some wide crosses.

Tissue Culture

Tissue culture includes *in vitro* culture of embryos, protoplasts, somatic cells, anthers, and microspores. There are mainly three kinds of applications of tissue culture in rice breeding. The first is doubled haploid (DH) production, which consists of anther and microspore culture. Rice anthers, of which the microspores are at the middle to late single nucleus stage, often after subject to a 1 week cold pretreatment, are cultured on specific medium, and haploid plantlets are

induced from the microspores. The microspores could also be dispersed into culture medium and then cultured in liquid. A high percentage of regenerated plantlets is spontaneously doubled in chromosome number, and thus become DH plants. The main advantage of DH technology is its ability to produce homozygous plants from any heterozygous breeding materials; this greatly accelerates the breeding process and shortens the breeding cycle. Additional advantage of DH technology is that the dominant effects are removed in DH lines, which is of paramount importance for selection of traits contributed by recessive genes. Although anther culture has been practiced in many countries and a large number of rice varieties have been developed, its potential has not fully been realized. The majority of indica rice varieties, which cover most the rice cultivating areas worldwide, are recalcitrant to anther culture.

The second application comes with genetic transformation. In the 1980s, protoplast transformation had been unanimously believed to be the only way to produce transgenic rice plants. Therefore, protoplast culture has been widely studied in many countries, but only a few plants were regenerated. With the rapid progress of genetic transformation on rice intact cells and tissues in the 1990s, protoplast gradually phased out, and *in vitro* culture responsive explants, such as (immature) embryos and young panicles, are used in tissue culture for genetic transformation. A vast number of transgenic plants have been produced either for rice improvement or for genomic studies.

The observation on genetic variation among regenerated plants from *in vitro* culture has led to the third application. Such variation is now known as "somaclonal variations (SVs)." SVs are composed of genetic and epigenetic alterations in regenerated plants. Inheritable SVs become a unique source of genetic variation, and are used in rice improvement. *In vitro* culture combined with mutagenic treatment could further increase the frequency and range of variations in progenies of regenerated plants. This system is known as *in vitro* mutagensis. Instances of success with such a system is the development of a series of mutant hybrid rice varieties, e.g., II you 3027, Shanyou 371, and Xieyou 371 in China.

Genetic Engineering

Conventional breeding has been an effective means for developing high-yielding varieties; however, it has its own limitations. The transgenic approach provides a novel way for rice breeders to use genes other than those from rice and its relatives. With this technology, the rice breeder is now able to transfer and incorporate desirable genes into rice genome, no matter where the gene comes from. The evolutionary and taxonomic isolation is thus broken. Significant advances have been made in the genetic engineering of rice since the first transgenic rice plants reported in the late 1980s. Several transformation protocols have been deployed successfully for the introduction of foreign genes into rice.

More than 60 rice varieties, which belong to indica, japonica subspecies, and African elite rice, had been transformed with various of genes which confer important traits, such as herbicide resistance, disease and insect pest resistance, environmental stress tolerance, and nutritional quality. Among them, transgenic plants with the insecticidal gene from *Bacillus thuringiensis* (Bt) might be the best example on agronomical improvement.

Several insecticidal Bt genes have been transformed into various types of rice, and all showed great potential for controlling the most important insect pests in rice. The Bt gene encodes the delta-endotoxin highly toxic to lepidopteran insects. Transgenic rice plants with Bt gene have proven to be highly resistant to all lepidopterans, including stem borers such as yellow stem borer, striped stem borer and pink stem borer, and rice leaf folders in field trials. Therefore, it may lead to reduction of 1000 t of pesticide use in rice production every year. This is important not only for cost reduction in rice production, but also has huge health benefits.

The transgenic "Golden Rice" is another success of genetic engineering. The whole pathway of β-carotene biosynthesis was introduced into rice plants by simultaneously transforming of three foreign genes: one plant phytoene synthase (*psy*) gene originating from daffodil (*Narcissus pseudonarcissus*), one bacterial phytoene desaturase (*crt1*) gene originating from *Erwinia uredovora,* and the lycopene β-cyclase (*lcy*) gene originating from *N. pseudonarcissus*. The highest β-carotene content reached 1.6 μg per g in rice grains. It was estimated that 200 g of Golden Rice could give 100% of the recommended daily allowance of vitamin A; therefore, it has great potential for solving vitamin A deficiency related diseases, such as blindness, in developing countries.

Marker-Assisted Selection

Marker-assisted selection (MAS) is a novel technique of indirect selection of traits in rice breeding. Marker here refers to all kinds of DNA markers, usually visualized by the polymorphisms of a DNA sequence. Restricted fragment length polymorphism (RFLP) is the first extensively used DNA marker; many other types of DNA markers have been developed during

the past 10 years, mainly PCR-based markers, such as (randomly amplified polymorphic DNA (RAPD), sequence characterized amplified region (SCAR), sequence tagged sites (STSs), and simple sequence repeats (SSRs) or microsatellite.

MAS has many advantages over phenotypic selection in rice breeding. DNA markers closely linked to important gene offer a tool for dissecting the genetics of complex traits and for transferring the identified loci into elite breeding lines. MAS is a more attractive approach when a few quantitative trait locus (QTLs) control a significant portion of the variability of one trait under selection. MAS is also favored when the traits being selected for have low heritability or are expensive and time consuming to measure. Compared to RFLP marker, microsatellite markers are probably the most promising markers for MAS in rice. These markers are highly polymorphic, and are now abundantly available for all rice chromosomes. Rapid DNA extraction methods developed for rice leaf tissues, or seeds are likely to work well with microsatellite markers for MAS. A prerequisite to using marker in such selection is that they should be closely linked to the precise phenotype or QTL of interest and polymorphism for the markers between the parents. MAS will certainly provide solutions to most problems associated with breeding improved for abiotic stresses. MAS techniques for bacterial blight and blast resistance, tolerance of flooding, and salinity are in progress.

Chinese Food Uses

S Lu, National Chung Hsing University, Taichung, Taiwan

Introduction

That rice culture has had a direct and significant impact on Taiwanese, and southern Chinese culture is a historical fact that could not be ignored. The Chinese proverb "Sow in spring, plow in summer, harvest in fall and store in winter" originated from and referred to rice culture which can be traced back to 4000 BC. Of all rice, ~90% is consumed as cooked whole kernels, and the rest is milled to produce flour, which is used to make cakes, desserts, and snacks for special feasts or celebrations.

In the USA, rice is usually classified by the length of grains, i.e., short, medium, and long. Both medium and long grain rice are produced in southern states and all grain types in California. In Taiwan, short grain *japonica* nonwaxy rice is produced throughout the island mainly in the southwestern plain area. Of this ~10% is of long grain *indica* rice, waxy *indica*, and/or waxy *japonica* varieties. Most short grain varieties are round or bold, and the long grain varieties are slender.

The two topics covered in this article will be how to mill rice to flour and an introduction to rice-based foods. Most of the rice foods are made from either nonwaxy *indica* or waxy *japonica* rice only, and some others are made from waxy *indica* type of rice.

Milling and Starch Isolation

Rice is milled or ground to flour or a coarse meal in some Asian countries as part of the process for making traditional rice dishes that resemble baked or steamed products. Rice flour used in processed food, which includes cereals, soup, snacks, candy and others, is estimated to have been 12.2 million cwt in 1990/91, over 21% of total domestic demand for milled rice. Official Taiwan markets statistics indicates that ~0.9 million cwt of rice flour is consumed annually, primarily in desserts and snacks. Of the total production, ~30% is used in making noodles, including rice noodles, "Bi-Tai-Ba," in main dishes.

One thousand years of milling history have produced three different milling processes: dry, semi-dry, and wet milling (Figure 1), which, depending on the amount of water used, yield different flour varieties. Properties and textural differences of rice flour are directly related to some of the inherent characteristics of starch, particularly the amylose content. Rice starch has more combinations of physico-chemical properties than other cereal starches. The amylose content of rice starch, which ranges from trace amount in waxy types to more than 30% in some nonwaxy *indica* varieties, plays an important role when rice flour is used as a thickener in food production. Some *indica* varieties, because of their higher amylose content (>27%), cause the product to be firmed or thickened, which produces a rigid gel during storage. Thin and wide rice noodle producers and rice cake manufacturers prefer high amylose *indica* varieties, such as Tainung Sen 19 and Taichung Sen 17. The starch gel of the flours from medium or short grain *japonica* variety is more stable than that of high amylose *indica* rices and is preferred in the production of puffed rice cakes and rice cracker, such as popular snacks in Japan, "Sen Bei" and "Arare." The waxy *japonica* rice demonstrates a stickier cooked product than the waxy *indica* variety. Viscoamylography, a rapid viscosity analysis (RVA) or a differential scanning calorimeter (DSC), would test and determine the damage starch produced and gelling or pasting behavior. These measurements are important in choosing the type of rice for the manufacturing of the rice flour. In addition to inherent preprocessing starch properties and storage conditions, methods of milling or grinding and pretreated rice kernel profoundly affect the physicochemical and functional properties of rice flour. Complementary quality control tests – such as protein, ash, and microbial content tests – should be performed on the rice flour, as flour gleaned during the milling process is used to produce other food products, i.e., baby cereal and processed products.

Rice Starch

Starch is a reserve carbohydrate found mainly in cereals, roots, tubers, and fruits and sometimes in the pith of plants. Usually it is associated with fats and inorganic salts, such as phosphorus. Rice starch granules are compound starches, varying in size from

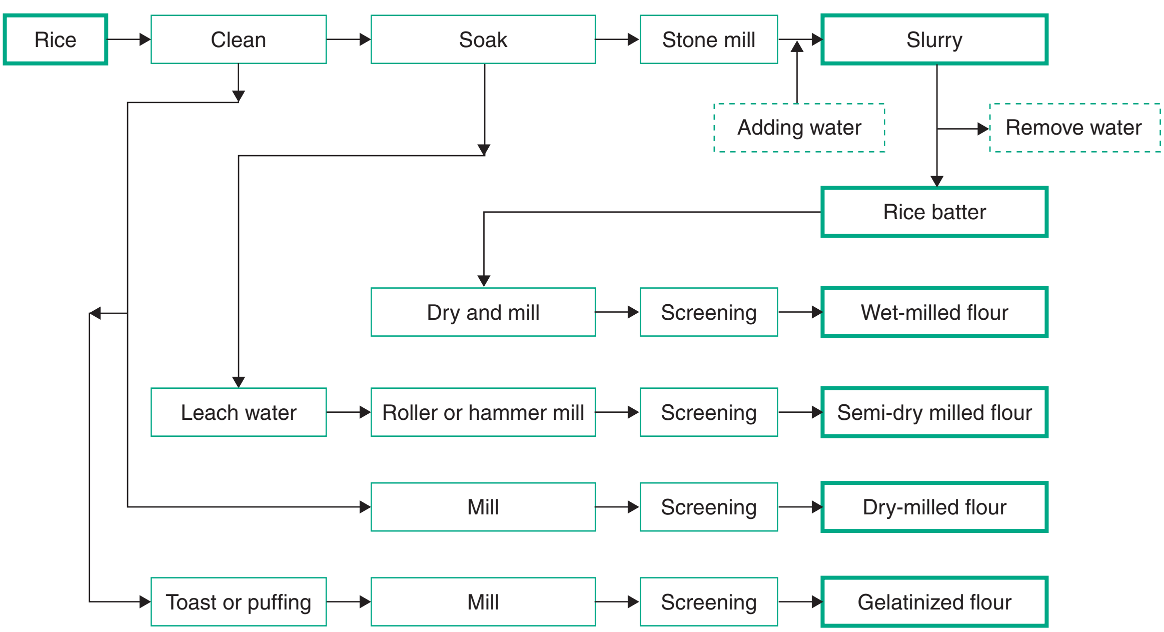

Figure 1 The flowchart of dry, semi-dry, and wet milling. (Reproduced with permission from Chen JJ (1995) *Studies on the Physicochemical Properties of Waxy Rice Flours by Different Milling Methods*. Master thesis, Chung-Hsing University, Taichung, Taiwan.)

3 to 10 μm. A starch granule is a homopolymer of α-D-glucopyranoside units. The linear polysaccharide, amylose, has a degree of polymerization on the order of several hundred glucose residues connected by α-D-(1,4) glucoside linkage. Amylopectin, a branched polymer, has a degree of polymerization on the order of several hundred thousand glucose residues, while the branched points are α-D-(1,6)glucoside linkage.

Commercial preparation of rice starch is not a dominant product because of its higher cost, when compared to corn, wheat, and tapioca starches. In Belgium, Remy Industries produce 75% of the world supply of rice starch. Rice starch has more combinations of physico-chemical characteristics than other starches. The amylose content of rice starch, which ranges from trace amounts in waxy types, to more than 30% in some nonwaxy *indica* varieties, must be considered when using rice flour as a thickener in food production. Some *indica* varieties, with an amylose content of more than 27%, cause the product to harden or thicken and produce a rigid gel during storage.

The common methods of preparing rice starch are by alkali or DOBS extraction. An older process for manufacture of rice starch is dodecylbenzene sulfonate (DOBS) treatment. The newer process of preparing is by NaOH extraction of the protein. Milled or broken rice kernels are steeped in 5 times its weight of 0.1–0.2% NaOH for 24 h at 40°C to soften the kernels and aid protein removal at the first step. Caustic treated kernels are washed and mixed with five parts of 0.1% NaOH and then stirred for 24 h. Soaked rice kernels are ground into flour and cell walls are removed by screening. The starch slurry is allowed to settle and the supernatant solution, which contains most of the protein, is removed. Starch granules are washed with water; decanting is employed to remove soluble materials. Centrifuging dewaters washed starch; complete removal of residual alkali is an important step. The starch slurry is put in an oven to dry-down the moisture to ~10%; the rice starch cake is ground to the desired particle size and sieved.

The starch properties measured by differential scanning calorimetry (DSC) showed that gelatinization temperature and enthalpy values were significantly correlated for these flours. The lower enthalpy values for dry-milled flour give an indication of relative high starch damage that occurs during milling.

Rice-Based Food Products

This article will not pay attention to the rice crackers, because they are the major and traditional baked snack food in Japan (Figure 2). Instead, the rice food which is consumed by the Chinese or overseas Chinese community will be emphasized. In terms of expanding into industrial scale, several discouraging factors come into play. The main obstacle is the lack of well-formulated machinery manufacturing processes. Other concerns include governmental controls over the distribution and price of rice, which limit the accessibility of raw materials to rice industry. The rice food products are classified into: (1) products using whole grains, such as puffed rice items, and (2) products using flours prepared before and after cooking.

Puffed Rice

Puffed rice products are common in Taiwan. The kernel puffing process involves frying or by high pressure.

Gun-puffing and Mi-Hua-Tung Gun-puffing cake and "Mi-Hua-Tung" are typical Chinese rice snacks made from puffed rice mixed and molded with syrup, sugar, peanut, and flavoring. *Japonica* type nonwaxy as well as waxy rice varieties are preferred for gun puffing. Waxy-type rice has higher water absorption index and water solubility, resulting in a soggy texture and eating quality, so the best choice for gun puffing is the low amylose content (below 20%) *japonica* rice. About 600 g of the rice with 14% moisture is fed to the gun, in which pressure is built up to 10–12 kg cm^{-2}, and then suddenly released. The gun is preheated for a couple of minutes before the rice is put in. After a short cooking time, the gun is suddenly opened and puffed rice kernel is caught in a metal hopper. The puffed rice is mixed with sugar syrup or maltose syrup in a pan to make small square pieces, called gun-puffing cakes.

For Mi-Hua-Tung, the milled rice or brokens are washed, soaked in water, and passed through a steaming and drying oven. The cooked rice is dried to 10–15% moisture by a rotated dryer, and then fried at a temperature of 240–250°C for 10–12 s for puffing. The puffed rice kernel is mixed with maltose, starch syrup, and other ingredients and put through a molder, metal separator, and then packed.

Guo-Ba For "Guo-Ba," the rice grain is cooked first. There are two ways to cook the rice. Traditionally, the rice is soaked in water for 30 min, and then boiled or steamed by gas to obtain the whole grain cooked rice. All the water is absorbed by the rice during cooking period. For industry, the milled rice is soaked in an equal amount of water at room temperature for a couple of hours and then steamed in 18 psi pressure for 10 min. Selecting the proper *indica* waxy rice

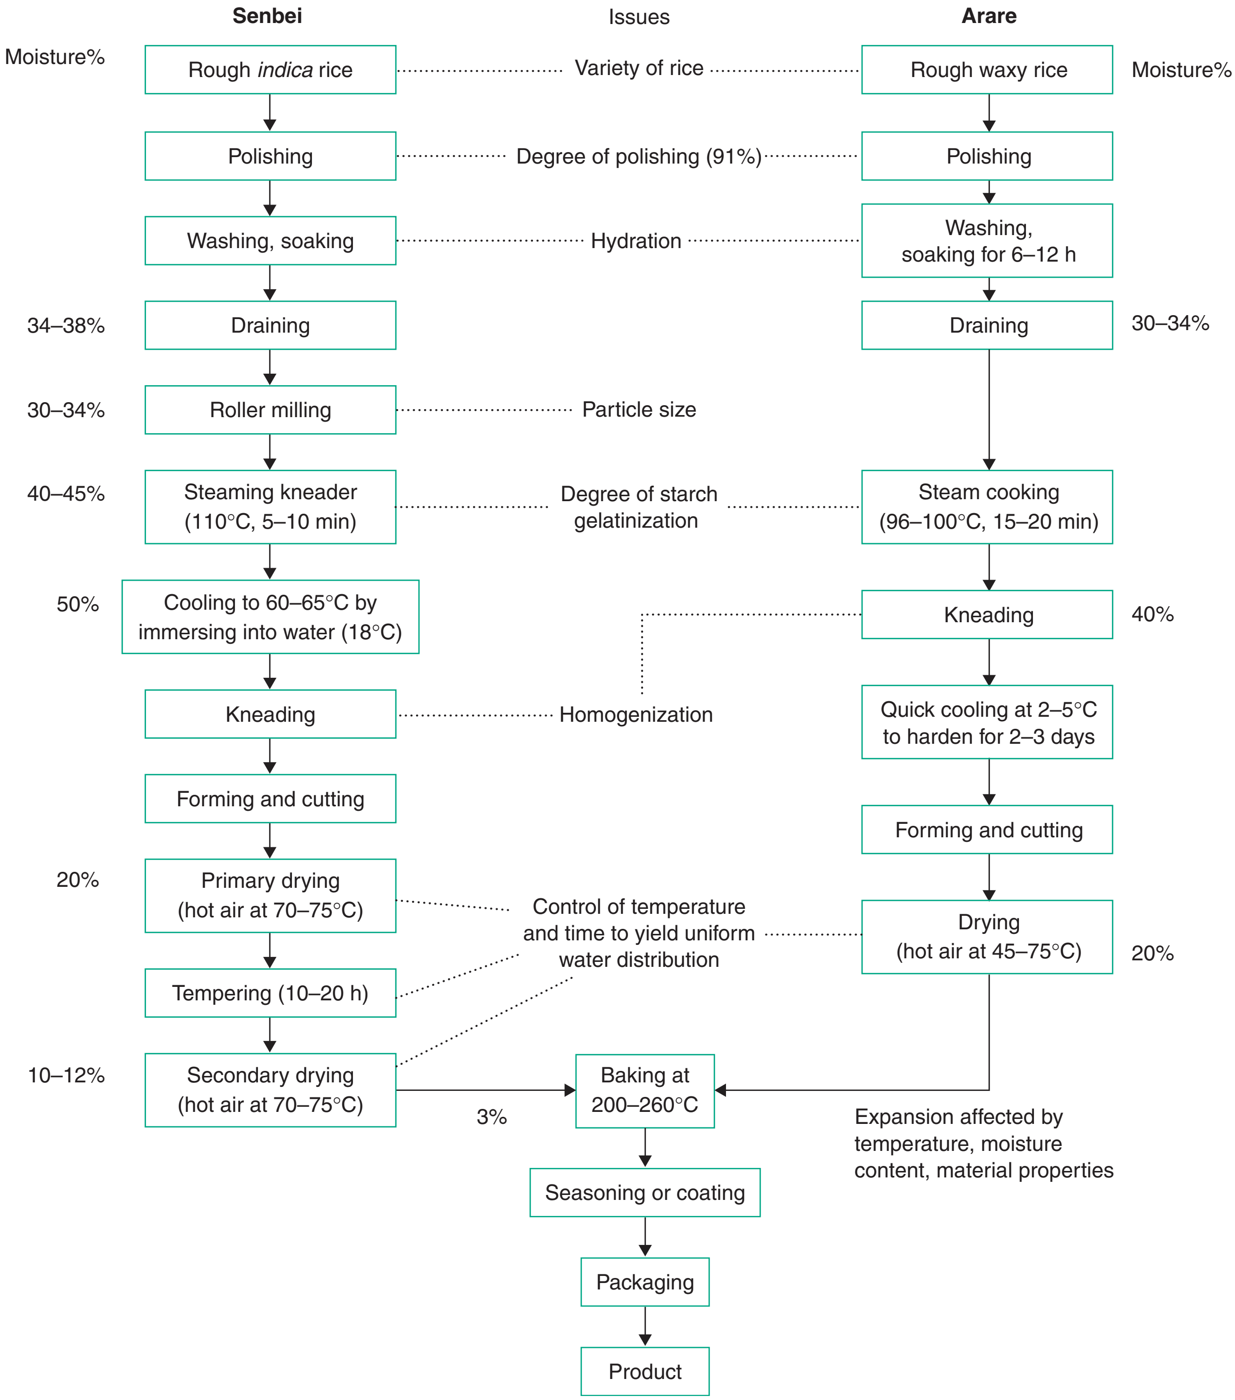

Figure 2 Manufacturing of "Senbei" and "Arare." (Courtesy of Yeh AY (2003). Preparation and application of rice flour. In: Champagne E (ed.) *Rice: Chemistry and Technology*. St. Paul, MN: American Association of Cereal Chemists.)

varieties and controlling the water–rice ratio are important in keeping the cooked rice from being too sticky or too soft. The heating conditions should be controlled to get the gelatinized rice or the cooked rice grain without scorches in the center location. Cooked rice is weighed and cut to rectangular pieces (10 grams each), put into 5 cm squares, and dried to reduce the moisture content down to ~12–15%. Dried products are then fried at 220°C by a deep fry conveyor for 4–8 s and then packed.

Rice Desserts and Sweets

Mogi In Taiwan, to the natives and to some extent immigrants, "mogi" is a very popular rice cake. It is prepared from *japonica* waxy milled rice (short grain) by washing, soaking, wet milling to flour, steaming at 100°C for ~45–60 min, kneading, cooling, dividing, and packing. Traditionally, the rice is pounded by wooden pestles in mortars. During this process, air is removed from the rice cake and a smooth texture is obtained. With mechanical kneading, the air bubbles easily get into the mogi which results in a rough surface of whiter appearance. Mogi is usually produced in a ball shape with mashed red beans or peanut grits inside and eaten as a snack.

New Year cake (Nien-Kuo) The short grain waxy rice is preferred to make "Nien-Kuo." The rice is soaked for a couple of hours and ground by stone mill to get slurry. The slurry is dehydrated either by centrifugation or by draining the slurry in a cotton cloth bag with heavy stones placed on the top of bag. The wet-milled rice flour containing ~45% moisture is mixed with sugar and water to get batter, and the ratio is 100 : 80 : 70 for flour, sugar, and water, respectively (Table 1). The batter is cooked in a steamer for 4–5 h, then cooled and packed.

Rice Noodle (Bi-Tai-Ba)

Indica rice varieties with high amylose content are preferred to make rice noodles because retrogradation is necessary. There are several rice noodle types, such as "Mi-Fen," "Bi-Tai-Ba," "Ho-Fen," etc., which are very popular in Taiwan, Japan, and among the overseas Chinese communities in Southeast Asian countries.

Mi-Fen Mi-Fen is a popular main dish in meals. Generally Mi-Fen is made in the dry state, and it can be steamed or cooked before serving. There are two procedures to make Mi-Fen, process A or B. Either of them can be selected.

Process A Cleaned rice kernels soaked in water for couple of hours are ground into slurry, the rice slurry is filled into a cloth bag, and the filled bag is pressed with a mechanical press or centrifugation to remove water. The dewatered rice solids are put in a heated mixer for 50 min and the rice solids are partially cooked to a soft mass (addition of cornstarch and/or wheat is optional). The soft rice mass is mixed a second time to further soften it. The soft rice mass is transferred to a presser to form thick sheets, followed by extruding the sheets into rice noodles, cooling, and loosening the extruded rice noodles immediately to avoid sticking together. The extruded rice noodles are steam-cooked for ~50 min, then cut into with a knife when still warm, shaped into bundles or blocks, and loaded onto trays in carts. Finally, shaped rice noodles are dried for 8 h, and cooled thoroughly before packaging into specific containers for retail or storage.

Process B Instead of soaking, grinding, and dewatering the rice, rice flour is used directly in mixing and partial cooking. The rest of the steps are essentially the same as process A.

Bi-Tai-Ba Bi-Tai-Ba is produced as a wet form of noodles, coarser and shorter. It is eaten with syrup and ice water in the hot season, but it also can be served with meat, green onions, or other seasoning. The traditional procedure to make Bi-Tai-Ba is explained as follows: Soaked rice kernels are wet milled to slurry, centrifuged to dehydrate the batter, heated to pregelatinize one-third of batter, the remaining two-thirds of the batter is extruded to string (3.0 mm in diameter), and finally, steamed, cooled, and packed.

Table 1 The quality characteristics of Nien-Kuo with different formula

Quality characteristics	*Ingredients ratio (sucrose : water : flour)*				
	11 : 4 : 10	*10 : 5 : 10*	*9 : 6 : 10*	*8 : 7 : 10*	*7 : 8 : 10*

Source: Lin JS (1993) *Studies on the Quality of New-Year Rice Cake Treated by Different Soaking Conditions and Dehydration Methods.* Master thesis, Chung-Hsing University, Taichung, Taiwan.

Recently, the extruder method has been used to make Bi-Tai-Ba. Dry-milled flour with 38% moisture is fed to a single screw extruder, which has three barrel sections, with temperature set at 130°C, 100°C, and 50°C, respectively.

Ho-Fen Ho-Fen making is similar to Bi-Tai-Ba; it is produced in both wet and dry forms of noodle, more thinner (1–2 mm thick) and wider (1 cm) rice stripes.

The basic steps in the making of traditional Ho-Fen is described as follows: prepare rice slurry with rice flour and water, put a small amount of oil on stainless trays to coat the trays evenly, pour rice slurry on the trays to form a thin layer (~1–2 mm thick). Steam the trays of thin layers of rice slurry to gelatinize the starch for ~5 min, then remove the trays as soon as possible from the steamer and cool down to the room temperature. Roll up the gelatinized rice sheet from each tray with a spatula (~10 cm in depth), and cut the layered rice sheets into 1 cm wide stripes. For long-time storage, dry the moisture to ~10% water-content with a mechanical oven drier or any such aid.

Fa-Kuo (Rice Muffin)

There is another kind of muffin-style rice food, "Fa-Kuo," in Taiwan and Southeast Asian countries. *Indica* rice is preferred to make this kind of food. Dried or wet-milled rice flour (100 g base) is mixed with 50–80% sugar and 3.5% leavening agent with or without red color additive, and water is added to the tune of 120% to make batter. The batter is put into a bowl, steamed for ~20 min, and then cooled. Fa-Kuo is prepared from wet-milling flour by two steps of high-speed mixing to get better eating quality than one-speed mixing procedure. The red-colored Fa-Kuo is usually prepared for celebration and festivals, since it is a symbol for luck and promotion in one's profession. During the time of Chinese New Year every family will have Nien-Kuo and Fa-Kuo.

Bowl Rice Curd

It is a very traditional and popularly consumed breakfast food item in the south of Taiwan. *Indica* rice flour is preferred to make bowl rice curd. The procedure is as follows: Milled rice kernels, homogenize, take 1/3 of the slurry to heat for partial gelatinization, mix remaining 2/3 portion, put in bowl and add other ingredients (chopped pork, salt, fried red onion, black pepper, seasoning etc.), steam for 15 min and, finally, pack the product.

Rice Cracker

Japonica and/or waxy rice varieties are preferred to make rice cracker. Cleaned rice kernels are soaked in water for a couple of hours, and ground in a stamp mill or pulverized in a roller mill. The fine particle rice flour is fed into a steaming kneader or cooked in a steamer for 15–20 min to gelatinize the starch, then cooled down to 60°C, and the dough is sheeted to plate form and cut to pellets. The pellets are dried until only 20% moisture content remains, tempered at room temperature for ~1 day, and then dried at a certain temperature until the moisture content drops to 10%. The dried pellets are then baked in an oven at a temperature ranging from ~200 to 260°C, thereafter, the expanded final product has a moisture content of ~3–5%.

Miscellaneous Products

There are several rice products, which are not major consumption for Asian people, and will not be attempted to introduce in this article. These products include parboiled rice, breakfast rice cereals, canned rice, easy-to-cook brown rice, rice bran oil and yeast-fermented rice cake.

Summary

Rice-based food products require specific physicochemical characteristics to produce the required eating qualities. There are several major factors affecting the cooking or eating qualities as considered by the end user, which include the aging or storage conditions of rice grains, rice varieties, amylose content of starch, degree of milling, as well as milling methods.

Wildrice, *Zizania*

E A Oelke, University of Minnesota, St. Paul, MN, USA

Introduction

Wildrice (*Zizania* sp.) is in its infancy in cultivation and domestication compared to other cereals such as rice (*Oryza sativa* L.). Rice has been under this process for a few thousands years BC. In the North American continent, the Native Americans did some expansion of natural stands by hand seeding new lakes and areas of lakes with sparse stands. But it was not until 1950 that a 0.5 ha area in Minnesota was specifically constructed to grow wildrice. Subsequently, more hectares were developed and some breeding efforts were initiated in the early 1960s with a full-scale breeding program initiated in 1972 by the University of Minnesota. Today wildrice is cultivated in Minnesota, Wisconsin, California, Oregon, and Idaho in the US, and in Hungary and Australia. The Canadians have expanded lake production by seeding new lakes in several provinces. The natural stands as well as newly seeded lakes in Canada are harvested by airboats with catchers attached to the front.

There are three species of wildrice that grow naturally in the North American continent: *Zizania aquatica* L., *Zizania palustris* L., and *Zizania texana* A.S. Hitchc. *Z. aquatica* grows along the eastern seacoast and has thin kernels. *Z. palustris* grows around the Great Lakes region and has large seeds. (It was gathered by Native Americans for hundreds of years as a food source.) Both of these species are annual aquatic grasses. *Z. texana* is a perennial with small seeds and grows only in a small area in Texas. *Z. latifolia* Turcz. grows in Asia, and the base which is infected with a fungus is harvested and used as a vegetable, "Makomo-taki."

Since wildrice is a recently cultivated cereal grain and in the process of domestication, the purpose of this article is to acquaint the reader with this new crop. Wildrice is cultivated using similar practices as is used for lowland rice, i.e., it only grows in flooded soils. Harvesting the newly developed varieties is done with combines similar to rice in the US. Processing is different, however, giving wild rice its unique roasted flavor. The nutritional value of wildrice is considerably better than rice having nearly twice as much protein and an amino acid complex similar to oats. Wildrice is often mixed with rice and served as a blend. The pure product serves as a side dish similar to potatoes or rice.

Continued improvement in yield and increased production should make wildrice more available in stores and restaurants not only in the US but also in other countries.

Wildrice Species

Wildrice was first classified by C Linneaus, in England in 1753. He used the description sent to him by J F Gronovius, Leyden, Holland. Gronovius described a plant sent to him by John Clayton which he collected in Virginia in 1739. Based on the plant's description, C Linneaus gave the plant the binomial *Zizania aquatica* L. The original plant specimen is preserved in the Gronovian Herbarium in the British Museum of Natural History in London, England. *Zizania* is a small genus of aquatic grasses in the tribe *Zizanieae*. Rice, *Oryza sativa* L., belongs to the tribe *Oryzeae*, which precedes the tribe *Zizanieae*. Both wildrice and rice belong to the grass family, Gramineae, and the subfamily, Poacoideae. Oats and barley are also in the Poacoideae subfamily. The above hierarchical classification is presented in *Gray's Manual of Botany*, eighth addition, by Fernald (1950). However, in more recent publications *Grass Systematics* by Gould and Shaw in 1983, second edition, and *Flowering Plants of the World* by Heywood (1993) both wildrice and rice are classed in the family, *Poaceae*, subfamily *Bambusiodeae*, and in the tribe, *Oryzeae*. Subsequently, wildrice growing naturally in lakes and rivers was classed into three different species by Linneaus and others. They are two annual species *Z. aquatica* L. and *Z. palustris* L. and one perennial species, *Z. texana* Hitchc. The distribution of these species in North America are shown in Figure 1.

There are two varieties of *Z. aquatica*, *aquatica* and *brevis*. They are annual plants that grow along the eastern Atlantic seacoast. The seed is long and thin and generally not harvested for food. There are two varieties of *Z. palustris*, *palustris* and *interior*. Both of these annual plants have relatively large grains and have been harvested as food for centuries by Native Americans. These two varieties grow naturally in the north central areas of North America. Today the best natural stands occur in the states of Minnesota and Wisconsin in the US and in the provinces of Manitoba and Ontario, Canada. A second perennial species has been identified in Asia. It is classed as *Z. latifolia* Turcz. There are accounts that the grain has been used by the elite as a special food. However, today in Asia the base of the plant, which is infected with a fungus, is used as

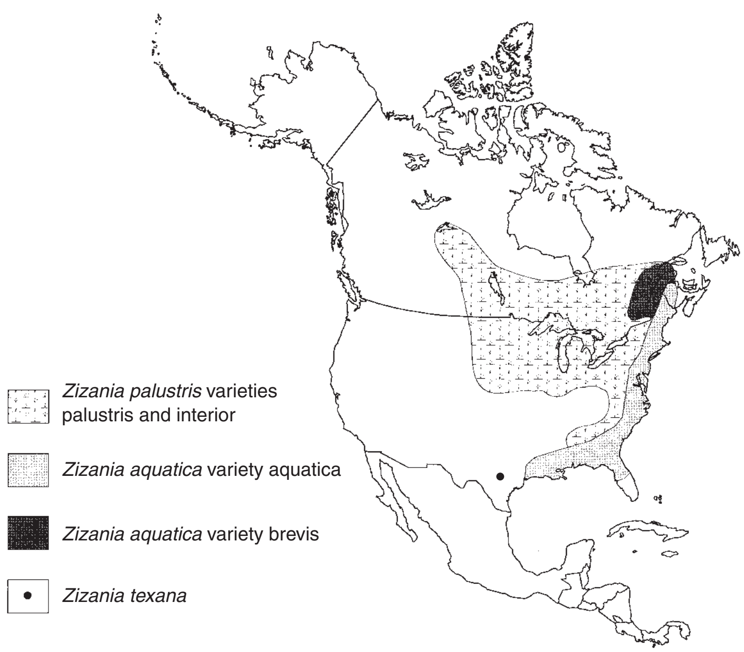

Figure 1 The natural distribution in shallow lakes and rivers in North America of the three species of *Zizania*. (Reproduced with permission from Oelke EA, Porter RA, Grombacher AW, and Addis PB (1997) Wild rice – new interest in an old crop. *Cereal Foods World* 42: 234–247. Minneapolis: American Association of Cereal Chemists.)

Table 1 Description of *Zizania* species

Species name	*Description*
Zizania aquatica var. aquatica L. southern wildrice	Annual, tall, large panicles, many branched florets. Grows in muddy shores of streams in southern Ontario and Quebec, southward to Florida and Louisiana. Average seed size: 14.3 mm long and 0.9 mm diameter.
Zizania aquatica var. brevis, Fasset, estuarine wildrice	Annual, short, small panicle with few branched florets. Grows in tidal areas of St. Lawrence River estuary. Average seed size: 6.7 mm long and 1.0 mm diameter.
Zizania palustris var. palustris L. northern wildrice	Annual, height ranges from short to tall, slender few-flowered panicle. Grows in water up to 120 cm deep in southern Canada from New Brunswick to Manitoba and northern US states. Average seed size: 16.7 mm long and 1.4 mm diameter.
Zizania palustris var. interior (Fassett), Dore, interior wild rice	Annual, medium tall, medium to large panicle with numerous florets. Grows in water up to 30 cm deep along rivers in southeastern Manitoba and adjoining Ontario and in the North Central States. The germ plasm of this species and variety has been used to develop varieties for cultivation. Average seed size: 10.7 mm long and 1.8 mm diameter.
Zizania texana A.S. Hitchc., Texas wildrice	Perennial, decumbent with many long stems, panicles short, short seeds. Grows only in a localized area in San Marcos River in Texas. Average seed size: 6 mm long and 1.2 mm diameter.
Zizania latifolia Turcz. Manchurian waterrice	Perennial, spreads by subterranean runners, tall, medium panicles, seeds short to medium in length. Native grass of Manchuria, Korea, Japan, Burma, and northeastern India. Base of plant often becomes infected with a fungus which is used as a "vegetable" delicacy. This species is commercially grown in Japan, Korea, and China for its vegetable called "Makomo-taki." Average seed size of collections from Japan: 7 mm long and 1.3 mm diameter.

a vegetable, "Makomo-taki." A brief description of each species is given in Table 1.

Historical Use of Species

Zizania palustris L.

The large seed, 8–16 mm long and 1.2–2.5 mm in diameter, has been harvested from lakes and rivers in the Great Lakes Region by the Chippewa and Menomini Native American (First Americans) tribes for centuries. After harvest it was processed and stored and used as a carbohydrate source for the long, cold winters. Many battles were fought for control of the prized wildrice stands. In most cases the Chippewa ended up controlling the wildrice stands. The Ojibway name for wildrice is "Manoomin" meaning good berry or good seed, but the exact meaning is not agreed upon. The early explorers, both English and French, who often traded with the Ojibway, gave various names to this plant; some were Indian rice, wild rice, Canadian rice, squaw rice, water oats, march oats, and water rice. The French explorers called the plant folle avoine, fools oats or wild oats. The name which was most commonly used was wild rice and is used in the trade today. To avoid confusion with the weedy strain of rice, *Oryza*, writers often use the hyphenated, wild-rice, or the single word, wildrice. In this article the author is using the single word wildrice.

Today stands of wildrice on reservations in Minnesota and Wisconsin are controlled by Native Americans, but in lakes and rivers outside of the Reservations, the stands are controlled by the departments of natural resources. In Minnesota and Wisconsin, a license is required by everyone to harvest from lakes and rivers, not on Reservations. Today, natural stands in Minnesota are harvested, by law, in the traditional method using a flat bottom boat or canoe. The canoe is pushed through the stand by one individual using a long pole while the other individual uses two flails (knockers) to knock the grain into the canoe. Since the grain ripens at different times on the same panicle and easily falls (shatters) from the plant when mature, stands are harvested by this method every other day for a period of 2 weeks. Enough grain falls back into the water before and during harvest to reseed the lake or river for the next year. Figure 2 depicts the traditional harvest method. In Canada, natural stands are generally harvested by airboats fitted with a grain catcher onto the front.

The traditional method of processing the harvested wildrice was to lay it on the ground for drying since the grain has ~40% moisture when harvested. Later the Native Americans used an iron kettle over a fire to dry (parch) the grain

Figure 2 The traditional way (canoe and flail) of harvesting natural stands of wildrice. One individual (standing) propels the canoe through the stand while the other uses two flails (knockers) to remove the grain from the stalks. (Photograph by Oelke EA.)

Figure 3 The traditional method of drying wildrice grain in a kettle above a fire. The grain is stirred while drying. (Photograph by Oelke EA, appeared in Oelke EA, Grava J, Noetzel D, Barron D, Percich J, Schertz C, Strait J, and Stucker R (1982) *Wild Rice Production in Minnesota*. Extension Bulletin 464, Agricultural Extension Service. St. Paul: University of Minnesota.)

Figure 4 The traditional way (jigging) to remove the outer hull of the wildrice grains. The individual walks in place to rub the grain against each other and also the kettle. (Photograph by Oelke EA, appeared in Oelke EA, Grava J, Noetzel D, Barron D, Percich J, Schertz C, Strait J, and Stucker R (1982) *Wild Rice Production in Minnesota*. Extension Bulletin 464, Agricultural Extension Service. St. Paul: University of Minnesota.)

(Figures 3 and 4). The hulls (lemma and palea) were removed from the warm grain by placing it into a round bottom container or leather lined hole and then walking in place (jigging) in the container. The chaff was removed by tossing the grain into the air (winnowing) and allowing the wind to blow away the lighter chaff. The heavier grain was caught in the container. Very little grain

harvested from natural stands is processed in this manner today. Most of it is processed with mechanical equipment as described later.

***Zizania aquatica* L. and *Zizania texana* Hitchc.**

The seed from these species is either too thin or small to make it worthwhile to harvest as a food source. *Z. texana* is on the endangered species list.

***Zizania latifolia* Turcz.**

This species is a perennial and is a native grass of Manchuria, Korea, Japan, Burma, and northeastern India. The plant generally is not used for grain production but grown commercially for its vegetable delicacy, especially in Japan, Korea, and China. The base of the plant becomes infected with a fungus. The infected base of the plant is harvested and eaten as a vegetable. In Japan they call the vegetable "Makomo-taki." The infected part is also dried and allowed to develop spores. The spores are then used by artists to develop lacquered, antique-looking woodwork, such as plates and small boxes (Figures 5 and 6).

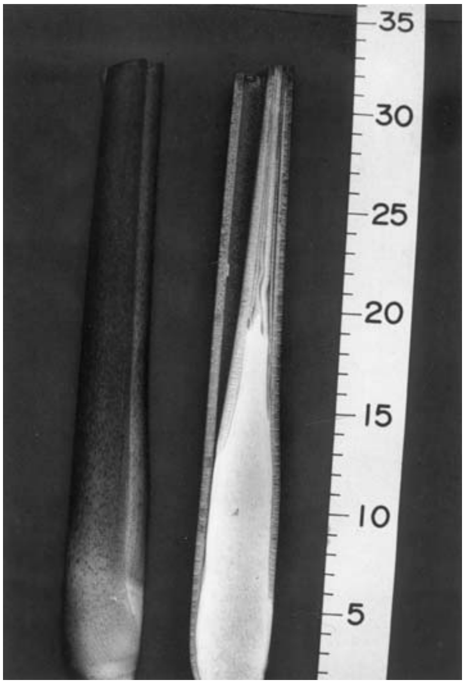

Figure 5 The base of the stem of *Zizania latifolia* which is infected with a fungus. This base is harvested especially in Japan and used as a vegetable "Makomo-taki" delicacy. Numbers are in centimeters. (Photograph by Oelke EA, appeared in Oelke EA, Bloom PR, Porter RA, and Liu Q (1999) Wild rice plant development and seed physiology. Cultivation of *Zizania palustris* L.

Domestication versus Cultivation

The expansion of this species of wildrice represents one of the largest modern efforts to domesticate a cereal grain. Cultivation usually is defined as annually harvesting the grain from a plant without annual sowing, through the germination of seeds which fall onto the soil. Thus, even the Native Americans did some form of cultivation but under natural conditions. Most crops are now truly domesticated, which means they depend entirely on human care for their perpetuation. Wildrice is not far removed from the cultivation phase. Varieties are being developed that shatter less than the plants growing in the lakes and rivers. They also produce more grain per hectare but still only 10–15% of that produced by *Oryza* (rice).

History of Cultivation/Domestication

Rice (*Oryza*) has been under the cultivation/domestication process for some thousands of years before

Figure 6 The Japanese farmer on the right is growing *Z. latifolia* for its "Makomo-taki" production. (Photograph by Oelke EA, appeared in Oelke EA, Bloom PR, Porter RA, and Liu Q (1999) Wild rice plant development and seed physiology. In: Williamson LS, Dlutkowski LA, and McCammon Soltis AP (eds.) *Proceedings of the Wild Rice Research and Management Conference*, pp. 54–67. Odanah, WI: Great Lakes Fish and Wildlife Commission.)

Christ. Native Americans did some seeding of lakes, thus did some cultivation, but relied on natural lake structures. They seeded wildrice by mixing the seed into clay, rolling it into a ball and dropping the clay ball into the water resulting in some increase in natural stands.

Interest in cultivating this plant has been expressed for well over 100 years by businessmen and botanists. Early explorers collected seed for planting in Europe, but they failed. In 1828, Timothy Flint in *Geography and History* wondered why no attention was paid to this plant. In 1852 Joseph Bowron and in 1853 Oliver Kelly also thought about why this plant is not cultivated. In 1917 H B Williams and Z Durand started mechanically harvesting private land in Canada.

The first individuals to construct a field specifically to produce this aquatic grain were James and Gerald Godward. They grew a 0.5 ha field at Bass Lake near Merrifield, Minnesota. The first three years the Godwards had good crops, but disease destroyed the crop the fourth year. They continued their pioneering efforts and by 1958 had 50 ha diked for growing wildrice. Tom Godward, one of the sons, continues to grow wildrice today near Aitkin, Minnesota, with ~6–800 ha under cultivation. During the mid-1950s and early 1960s others started growing wildrice. In 1965, Uncle Ben, Inc. started contracting for production, which was a big impetus to produce wildrice. Today there are ~7000 ha in Minnesota, 5000 ha in California, with a few hectares in Wisconsin, Oregon, and Idaho in the US producing wildrice. Some production also is now taking place in Hungary and Australia (Figure 7).

Genetics and Breeding

Domestication of a wild species requires that plants are selected from wild populations that maintain their grains on the plant even after maturity (nonshattering). The grain also needs to mature uniformly and have more grain production in relation to vegetative production. One of the important factors in the domestication process was the discovery, in 1963 in a grower's field, of a nonshattering plant by two University of Minnesota scientists (Figure 8). Subsequently improved varieties were developed from this germ plasm by individuals, companies, and the University of Minnesota. Up until that time fields were planted with seed collected from lakes. These fields were harvested with picker/harvesters on tracks. The fields had to be harvested several times during a 2 week period without cutting off the plants. Yields with this method were only 168–224 kg ha^{-1} of unprocessed grain. Fields planted to the newer nonshattering varieties could be harvested once with a regular grain combine and yielded over 1700 kg ha^{-1}. The development of the nonshattering varieties resulted in a tremendous expansion of cultivatedhectares in Minnesota. Table 2 shows the cultivated wildrice production after processing for Minnesota and California since 1968.

Individual wildrice growers began their own selection programs to select better plant types in the 1960s and some are continuing today. The wildrice breeding program at the University of Minnesota began in 1972. It continues till today and is the only public wildrice breeding program in the US. To date, six varieties have been released all with some desirable characteristics needed to further the domestication of

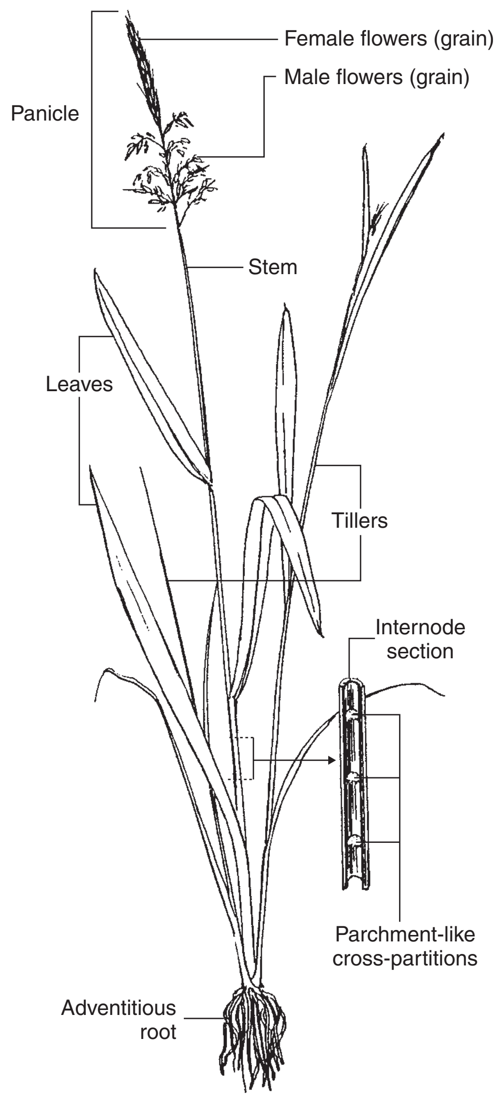

Figure 7 A drawing of a *Zizania palustris* plant. This type of plant is the one cultivated in commercial fields. (From Oelke EA, Elliott WA, Kernkamp MF, and Noetzel DM (1973) *Commercial Production of Wild Rice*. Extension Folder 284, Agricultural Extension Service. St. Paul: University of Minnesota.)

Figure 8 The panicle on the left is a nonshattering type while the one on the right is a shattering type. The nonshattering type can be recognized by loss of male flowers soon after pollen shed on the branch (lower) portion of the panicle. (From Oelke EA, Grava J, Noetzel D, Barron D, Percich J, Schertz C, Strait J, and Stucker R (1982) *Wild Rice Production in Minnesota*. Extension Bulletin 464, Agricultural Extension Service. St. Paul: University of Minnesota.)

wildrice. Improved shattering resistance is the primary goal, but disease resistance particularly to fungal brown spot on the leaves is a close secondary goal. Another goal is shorter plants with higher yields. Yields have nearly doubled from the original "Johnson" nonshattering variety developed from the nonshattering plants found in 1963. A private breeding program exists today in California which has developed varieties for their warmer and longer growing season. The genetic material for that program basically came from Minnesota. Thus far, all of the breeding is done by conventional selection and not genetic engineering. A program at Lakehead University, Thunder Bay, Canada, is ongoing to select types of plants that do well in specific lakes.

Cultivated wildrice (*Zizania palustris* var. interior and *palustris* L.) of North America is an annual diploid with a chromosome number of $2n = 2x = 30$; thus, it has 15 chromosome pairs. Compared to rice (*Oryza sativa*) wildrice has three more pairs of chromosomes and twice as much DNA content as rice. Recent (2000) research indicated that when total wildrice DNA was used as a probe in Southern hybridization to different Poaceae genera such as rice, oat, barley, wheat, and maize, there was a strong hybridization signal with rice, but relatively little with oat, barley, wheat, or maize. The greater DNA hybridization of wildrice reflects wildrice classification in the Bambusiodeae subfamily to which rice also belongs. The close relationship of wildrice to rice will benefit the mapping of genes in wildrice. Similar probes used for mapping genes in rice have been used in wildrice and some of the same genes have been found to be located in the same area in wildrice as in rice. Locating important genes such as seed shattering will facilitate the wildrice breeding efforts for domestication.

[a] Data provided by Minnesota Cultivated Wild Rice Council and California Wild Rice Advisory Board.

Figure 9 An aerial view of Minnesota wildrice fields after flooding in the spring. (Photograph by Oelke EA, appeared in Oelke EA, Grava J, Noetzel D, Barron D, Percich J, Schertz C, Strait J, and Stucker R (1982). *Wild Rice Production in Minnesota*. Extension Bulletin 464, Agricultural Extension Service. St. Paul: University of Minnesota.)

Cultivation Practices

Wildrice is well adapted to northern latitudes with its cooler climate. In southern latitudes of the USA, such as Arkansas, warm day and night temperatures speed up development resulting in a short, unproductive plant. The high humidity also results in severe leaf disease problems such as fungal brown spot (*Bipolaris* sp.). Varieties have been developed that grow well in the warm day but cooler night temperatures of northern California. Leaf diseases are not prevalent in northern California due to the low humidity.

The cultivation practices for wildrice are similar to rice in that the fields need to be kept flooded for the growing season except several weeks before harvest. Wildrice will grow well on organic or inorganic soils if nutrients are supplied. Wildrice requires less nitrogen than rice since it can get too tall and lodge if over-fertilized. It will grow in deeper and cooler water than rice; thus, water depth can be used as a means of weed control. Handling wildrice seed is critical in establishing fields. Wildrice seed must be stored wet and in cold (3°C) water for 3 months to release seed dormancy. In Minnesota, new fields are seeded in the fall and the fields flooded either in the fall or spring to a depth of 30 cm. In Minnesota, fields can be kept in production for 2–4 years. The second and succeeding years the fields seed themselves from shattered seed even when seeded to the newer more shatter-resistant varieties. In the Sacramento Valley of California, the fields are seeded each year due to loss of viability of the shattered seed. Seed has to be stored in cool wet conditions over the winter and then seeded the next spring. In the northern higher elevations in the valleys between Mount Lassen and Shasta, the production practices are similar to Minnesota (Figures 9 and 10).

Fungal brown spot (*Bipolaris* sp.) is a severe disease in Minnesota, but not a problem in California. The wildrice worm (*Apamea apamiformis* Guenee), which is the larval stage of the noctuid moth, is the most serious insect pest in the Upper Midwest but not a problem in California.

In Minnesota and California, fields are drained 3 weeks before harvest. Grain combines are adapted with large reels and tracks for harvesting wildrice. The grain has to be harvested at 30% moisture since shattering will occur if harvested at a lower moisture content. The grain is immediately transported to processing plants (Figure 11).

Processing

Processing consists of drying (parching), hulling, scarification, cleaning, grading, and packaging. When the grain arrives at the processing plant, it is put into piles or containers and kept for 1 or 2 days. Then the grain is put into rotating, heated drums (parchers) that will hold 225–370 kg. Drying the high moisture grain takes about an hour or more. The grain is dried to ~7% moisture. This moisture level is reached when the grain temperature in the drum reaches 135°C. Laser thermometers are used by some processors to monitor grain temperature. After parching, the hot grain is passed through a huller consisting of two

Figure 10 In Minnesota, fields in production for two or more years, the plant population is reduced by airboats. V-shaped knives mounted on the rear and spaced 15 cm apart are dropped into the water to the soil line which removes excess plants. Enough seeds, even from the nonshattering varieties, fall onto the soil before and during harvest to produce too many plants the following year. (Photograph by Oelke EA.)

Figure 11 Cultivated wildrice, nonshattering varieties, being harvested with a combine with full tracks and an enlarged reel. (Photograph by Oelke EA.)

rubber rollers going at different speeds. The light chaff is evacuated from the kernels and the hulled kernels are graded with graders and gravity tabels. Sometimes before grading, the kernels are scarified by passing through a tube with rubber paddles. This removes some of the darker, impermeable outer layer of the kernel to allow a faster cooking time. The parched, graded kernels can then be stored for future packaging (Figures 12 and 13).

Nutritional Properties

The wildrice kernel consists of a pericarp, aleurone layer, endosperm, and embryo. The pericarp and embryo each represent ~5% of the kernel weight.

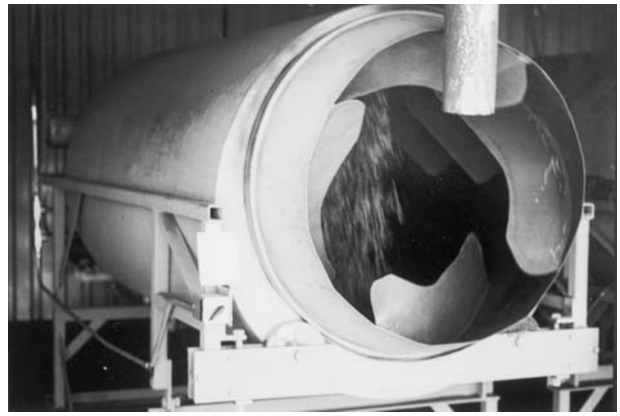

Figure 12 A rotating drum heated on the bottom to dry (parch) the wildrice grain. Modern processing is based on the principle of traditional methods. (Photograph by Oelke EA.)

Minneapolis: American Association of Cereal Chemists.)

The rest, 90%, is made up of the endosperm and aleurone layer.

The nutritional quality is very good for a cereal grain. It is equal to or better than other cereals such as wheat, barley, or rice. The protein content is about that of wheat (13–14%) while brown rice has ~8%. The sum of lysine, threonine, and

methionine content is similar to oat groats, which are considered one of the better cereals for humans. The mineral content of the wildrice kernel is similar to that of wheat, oats, and corn. Processed wildrice contains no vitamin A but is an excellent source of B-vitamins (Tables 3–5).

Wildrice has good antioxidant properties. There is considerable interest in antioxidants, which can slow diseases such as coronary heart disease and certain types of cancer. Hydrated wildrice mixed with ground beef had significant antioxidant activity. Recently, 2000, it has been found that consumption of cultivated wildrice by rats lowered their liver cholesterol. This needs to be confirmed in humans.

Markets and Uses

The cultivation of wildrice provided a large, consistent supply of wildrice compared to the inconsistency of that from natural stands. Today ~95% of the wildrice in the marketplace comes from cultivated fields. The wildrice market expanded rapidly during the 1960s through the 1980s primarily in the blend market. Sales increased an average of 15% per year when Uncle Ben, Inc., introduced the first package blend of wildrice, long grain rice, and herbs. Many other blends are now available including soups, vegetable-based side dishes, and convenience foods such as dehydrated mixes and frozen entrees. Today sales are increasing ~5% per year. The wholesale price per US pound of processed grain ranged from US$2.50 with a high of $5.15 in 1978 and then decreased steadily to about $1.40 in 2002 as increased supply came from cultivated fields.

Increased use of wildrice as a pure product as well as in blends should continue. In Minnesota, by law, the pure product has to be labeled “cultivated” if it is produced in cultivated fields and sold in Minnesota. Wildrice is a nutritious food and even though it is considered a gourmet food, it is not very expensive on a per serving basis. Quick cooking wildrice is now being developed and should expand the market. Production of wildrice should increase as new, better yielding varieties are developed. Domestication of the plant is in its infancy compared to other cereals, but rapid progress can be made using modern breeding and genetic techniques.

RYE

W Bushuk, University of Manitoba,Winnipeg, MB, Canada

Introduction

Rye, (*Secale cereale* L.), is a grass plant cultivated worldwide and used as grain and straw. The grain is second after wheat in the production of bread. It is also important in the production of mixed feeds for livestock and as feedstock for the distillation of rye whisky. Straw is used in livestock feeds, as bedding in animal husbandry, and as a building material (e.g., roof thatch, particle board, etc.).

Center of Origin and History

The primary center of origin of the rye plant is considered to be in the Anatolean Plateau of the Middle East, which is also the center of origin of wheat, barley, and oats. There is no evidence of rye cultivation in ancient Egypt. It is mentioned in early writings of northern Europe suggesting this as an important area of historic cultivation.

Cultivation of rye migrated from the center of origin to northern Europe in the first millennium BC. One possible route of migration is from Asia Minor to western Russia and from there, westward to Poland and Germany where it is highly adaptable and the grain well liked by the inhabitants. Another possible route of migration is from Turkey by way of the Balkan Peninsula to north-central Europe.

Rye was brought to North and South America by European settlers during the sixteenth and seventeenth centuries. At about the same time, its cultivation spread eastward in Europe to Siberia. During the nineteenth and twentieth centuries, its cultivation began in Argentina, southern Brazil, Uruguay, Australia, and South Africa. Today, rye cultivation, like that of wheat, is worldwide but the largest production is in Germany, Russia, Poland, Belarus, and Ukraine.

Botanical Classification

Rye belongs to the grass family Gramineae and the genus *Secale*. The most common cultivated species is *S. cereale,* which is presumed to have evolved from the wild perennial grass of the species *S. montanum.* Cultivated rye contains seven pairs of chromosomes belonging to a single genome designated by the letter R. Unlike the situation in wheat, the number of commercially grown rye varieties (cultivars) is relatively small. Rye cross-pollinates

extensively and is, therefore, difficult to maintain genetic purity.

Most of cultivated rye is fall-sown annual crop called "winter rye." Rye has excellent winter hardiness and therefore can be grown in areas where the climate is too severe for winter wheat. Spring rye is grown in some countries, e.g., Canada.

Worldwide Production and Trade

Worldwide production of rye grain declined significantly over the past decade (Table 1) and stabilized at 20 million ton (Mt), grown on ~16 million hectares (Mha), over the past 3 years for which statistical data is available. The decline, mainly due to gradual decrease in demand for both human and livestock consumption, has been achieved by a gradual decrease in the area harvested. Russia is the leading rye producer followed by Germany, Poland, Belarus, and Ukraine. Together they produce almost 80% of world rye grain. United States, Canada, and Turkey are significant contributors to the world rye stocks.

Rye ranks last of the eight cereal grains grown for human food (Table 2), the position it has occupied over the past four decades.

Most of the rye grain is used domestically. The following data was derived from recent international statistics. In 2001–02, of the total exports of ~1.6 Mt, European Union (mostly Germany) contributed 61% of the total. Ukraine had an excellent crop and was able to supply 28% of the world market. Canada contributed ~5% and Russia 3.4%.

Major importer of rye in 2001–02 was Japan, accounting for 27.05%, where it is used mainly for animal feed. Other significant importers are South Korea (13.52%) and United States (8.45%).

Plant and Grain Morphology

The mature rye plant has a slender, tough, fibrous stem (straw), and elongated leaves. Plant heights vary widely from ~30 cm to over 2 m. The inflorescence (spike) is long and slender with stiff long awns (beards). Rye grain (caryopsis) is arranged in pairs alternately on a zig-zag shaped rachis (Figure 1). The grain is covered with a lemma, palea, and a glume (chaff) which is normally awned. Like wheat, rye grain is free-threshing; the mature grain separates easily from the glume during threshing.

Rye grain (kernels) is more slender and longer than wheat ranging in length from 4.5 to 10 mm and in width from 1.5 to 3.5 mm. The grains are normally of grayish-yellow color but the color can vary widely depending on rye cultivar, region of cultivation, and harvesting conditions. As in wheat, a crease extends the full length of the ventral side of the grain. The surface of the grain is usually shriveled and has a rough texture. A single grain weighs ~20 mg.

Rye grains comprise three distinct morphological parts (Figure 2). They are starchy endosperm, 86.5%, bran (pericarp and testa), 10%, and germ (embryo and scutellum), 3.5%. In milling rye grain into flour, the bran and germ are separated from the endosperm, which is ground into flour.

Proximate Composition and Nutritional Properties of Rye Grain

The proximate composition of rye grain (Table 3) is typical of cereal grains with carbohydrate (nitrogen-free extract) being the main constituent forming ~80% of the grain. Starch is the major carbohydrate component. As in wheat and barley, rye starch is stored in the endosperm in two types of granules, large lenticular granules measuring ~35 μm and small spherical granules ~10 μm in diameter. In gelatinization properties, rye starch is similar to wheat starch; they have similar functionality in breadmaking.

Rye grain contains considerably more hemicellulose (pentosans) than wheat, 6–9% compared with

~2% for wheat. The hemicellulose contributes significantly to the functional properties of rye flour in bread-making where it interacts with the proteins and prevents their aggregation into gluten required for the viscoelastic properties of bread doughs.

Rye has some advantages over wheat in properties related to human nutrition. It is higher in lysine content to the extent that this amino acid is not the first limiting amino acid in rye as it is in other cereals. Tryptophan is considered the first limiting amino acid in rye. Rye flours are usually milled to a higher extraction rate, as they normally have higher dietary fiber content than wheat flours. The stronger flavor and gummier texture of rye-baked products are well liked by many consumers.

The mineral and vitamin content and composition of rye is similar to those of other cereals (Tables 4 and 5). Rye is considered a good source of thiamin, nicotinic acid, riboflavin, pyridoxine, panthotenic acid, and tocopherol. These constituents are mostly removed during milling of flour, as they are stored mainly in the germ and the aleurone layer of the grain.

Rye grain contains some constituents, which have antinutritional properties especially in animal nutrition where whole grain is used. These constituents include alkyl resorcinols, soluble hemicelluloses which interfere with feed digestion in monogastric animals, phytic acid which binds calcium and zinc, and trypsin inhibitor which interferes with the digestion of proteins.

Commercial rye grain is frequently contaminated with ergot bodies, sclerotia of the fungus *Claviceps purpurea* (Fr.:Fr.) Tul., which contain ergotamine (a toxic alkaloid), which, if consumed by livestock can cause abortions. The antinutritional constituents are of no significance in human consumption of rye products as they are either removed during milling or inactivated during baking.

Genetics, Plant Breeding, and Agronomy

Most of the commercial rye grown is the diploid *S. cereale* type. Attempts to develop tetraploid rye by doubling the number of chromosomes with colchicine have been unsuccessful. The resulting tetraploid was more susceptible to ergot and less cold-tolerant. Recently, breeders in Lethbridge, Canada, developed a hybrid between *S. cereale* and *S. montanum* as a potential perennial forage crop. Its productivity is relatively short-term (3–4 years) and this may limit its commercial production. Much of the research on hybrid rye is in Germany (Stuttgart) where most of the commercial crop is of the hybrid type.

Rye has been used extensively as a source of disease resistance in wheat-breeding programs. The disease-resistant genes are incorporated through a translocation of 1R chromosome into 1A or 1B

chromosome of wheat. Many commercial wheat varieties contain one of these two translocations.

Diploid rye is the starting species for the development of triticale, a hybrid of the alien genomes of rye and wheat. Triticale is gradually becoming a significant grain for food and feed uses.

Major rye-breeding programs are located in Germany and Poland. In most programs, grain

yield is the main breeding objective. The main quality characteristic that is selected for is high falling number (low alpha-amylase activity). As far as disease is concerned, the main efforts are on resistance to rust and *Fusarium* head blight. Snow mold is the third disease complex being tackled by breeding. A genetic engineering approach, which could potentially improve the baking quality of rye, is by replacing a secalin locus with the locus of wheat, which controls the $5+10$ high molecular weight glutenin subunits in wheat. In wheat, these subunits play a key role in bread-making quality. Preliminary results by this so-called interstitial interchange approach to rye-quality improvement are promising.

Agronomic practices and growing conditions for rye are similar to those for wheat, barley, and oats. Rye performs better than wheat on lighter soils and can tolerate higher levels of aluminum in acidic soils.

Grading Rye Grain and Primary Processing

Agricultural products, including grains, vary in composition and processing quality caused by fluctuations in weather conditions during the growing season. To facilitate marketing and processing the grain is graded, separated, or combined, into parcels of relatively uniform properties. In countries where rye grades exist, they are based on physical characteristics of the rye grain and on the presence of foreign contaminants. Test weight, a measure of bulk density related to milling quality, is the only grading factor that is measured objectively. All other factors are assessed subjectively by visual inspection. Normal or straight grades usually have a prescribed maximum moisture content; 14% in Canada and the United States and 16% in Germany. The number of grades of milling rye varies among countries. Germany (Table 6) has one grade, Canada has three, and the United States has five grades.

In grain commerce, rye is handled in bulk and transported by truck or locomotive. Rye for export must meet the importer standards for foreign contaminants and must be free of toxic substances. Export transfer is in bulk by cargo vessel or in containers if the shipments are small.

In transforming rye grain into food for human consumption, the primary processing step is milling the grain into a product called flour. Despite some

Table 6 German standards for milling rye[a]

Moisture content	Max. 16%

significant differences between the physical structure of rye and wheat, the milling processes for the two grains are similar. The first step is the removal of all undesirable contaminants. This is achieved by a series of special machines functioning consecutively. Differences in shape, size, density, and color are all used to improve the efficiency of the cleaning. The final step of the cleaning section is tempering which involves addition of water to toughen the bran and mellow the endosperm. Moisture levels for tempering rye are usually 1% lower than those used for wheat. Tempering periods are shorter because of the softer rye endosperm.

Because of the softer texture, rye endosperm releases more flour during the breaking operations and essentially no middlings require purification. Reduction is achieved by corrugated rolls instead of smooth rolls used for reducing wheat middlings into flour. Rye milling requires a larger sifting area than wheat because rye flour tends to clump because of its softer texture.

North American rye mills produce a small number of different grades of flour, usually three (Table 7). The main quality parameter is ash content. European rye milling is more precise. A modern German rye mill will produce as many as seven different flours designated by ash content and several types of meals processed by crushing and cutting over a range of particle size (Table 8).

Uses of Rye

Worldwide, over 50% of rye grain is used for the production of livestock feed. The key factors for this application are price, relative to other feed grains such as barley, energy per unit weight, and absence of antinutrients and toxicants. Ergot bodies must be removed by cleaning. Technology has been developed in the use of enzymes and other additives to mitigate the effects of antinutrients such as the soluble hemicelluloses. Rye grain imports by some countries, e.g., Japan and South Korea, are based almost entirely on the livestock-feed industry.

Bread and other baked products are the main food products in the major consuming countries – Austria, Belarus, Czech Republic, Germany, Poland, Russia, Scandinavian Countries, and Ukraine. Many types of baked products are made including bread from 100% rye flour, rye-wheat bread containing at least 50% rye, wheat-rye bread containing at least 50% wheat and at least 10% rye, whole meal rye bread, rye rolls, crisp bread, and pumpernickel. Crisp and pumpernickel breads have excellent shelf life. A new type of bread, made from partially sprouted rye, has been introduced in Moscow, Russia, for its unique flavor, texture, and nutritional quality. Many other products are available in regional markets made from various mixtures of whole meal, rye flour, and wheat flour.

In Canada and the United States, a wide range of rye products are available dominated by four basic types of bread: American rye bread, a light rye bread made from 15–40% rye flour and low-grade wheat flour; sour rye bread made by the sourdough process using various combinations of rye and wheat flours; pumpernickel bread with and without molasses: and sweet or pan rye made from rye (10–40%) and wheat flour mixtures. Bread from 100% rye is available from specialty bakeshops. Rye flour is also used in a large variety of snack foods.

Small quantity of rye is used worldwide in many other foods. These include rolls, sweet goods, breakfast cereals (mixtures, flakes, and bars) and as whole grain in specialty breads. The unique texture and flavor of rye is being used to advantage in many food products.

Worldwide, small quantity of rye is used in nonfeed and nonfood industries. Traditionally, rye straw is used on the farm as livestock bedding. In Canada, rye is fermented and distilled to give alcohol that is used as a beverage and in pharmaceuticals. Rye flour is used as an adhesive in the production of wallpaper, corrugated packaging materials, and plywood. The capacity of the rye plant to produce a large quantity of biomass on low-fertility soil has not been exploited by the biomass energy industry. The pentosan component of rye is used to make furfural, as starting material for many industrial chemicals. Rye plant has been reported as a significant component of a sustainable system of agriculture but its use in this way remains to be exploited. For additional information on rye, the reader is referred to the recently published monograph "Rye: Production, Chemistry and Technology."

S

SCIENTIFIC SOCIETIES ASSOCIATED WITH GRAIN SCIENCE

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The industries that grow, harvest, and process grain are big businesses worldwide, involving large numbers of people, including many scientists. It is important that these scientists should have the opportunities to interact with one another, to exchange ideas, to learn from one another, and importantly, to develop analytical methods that are accepted internationally (*see* **Appendix**: Test Methods for Grain and Grain-Based Products). Opportunities for these various activities are provided by specialist societies and associations ("learned societies"), with grain scientists as members, formed for the purposes of interacting with one another in their areas of expertise. In many instances, there is the added objective of providing a focus for interaction with the public in the area of specialization of each society.

Many such scientific societies have been formed, covering the wide range of aspects of grain science, from breeding, through agronomy and farming, to the chemistry of the harvested grain, to marketing and processing. Some of these societies are selected for description below, but the range covered is by no means comprehensive. In addition to scientific societies, there is an even greater number of trade associations, formed for the purposes of interaction at the technical and commercial levels, and for lobbying purposes. A list of many scientific and trade associations of the food industry has been assembled by the *New Products Magazine* (Stagnito Communications Inc., Deerfield, IL, USA, www.hoovers.com).

The activities of the scientific associations include the organization of conferences at which lectures are presented, where personal interactions can occur and where trade exhibits can provide information about the latest equipment and resources. Other activities include the dissemination of information via journals, books, and other publications, the establishment of professional standards of conduct and training, and the development of standard methods of analysis.

The Range of Societies

Prominent among these learned societies are those relevant to the quality and processing of grain. In particular, the American Association of Cereal Chemists (AACC) has a worldwide membership of scientists involved in grain production and processing. The International Association for Cereal Science and Technology (ICC), based in Vienna, Austria, is an international association committed to international cooperation through disseminating information and developing standard methods relevant to grain production and processing. There are also national bodies with similar objectives, such as the Chinese Cereals and Oils Association (CCOA), based in Beijing, China, and the Cereal Chemistry Division of the Royal Australian Chemical Institute, based in Melbourne, Australia. In addition, a range of societies caters for specific grain types or related processes, such as the National Oilseed Processors' Association.

Other societies have been formed for those involved in specific aspects of chemical analysis or individual classes of chemical compounds. For example, The American Oil Chemists' Society (AOCS), comprising some 5000 members worldwide, provides "a global forum for the science and technology of fats, oils, surfactants and related materials." Furthermore, AOAC International is an "internationally recognized organization with 120 years of experience in validating and approving analytical methods for foods and agriculture." In both these cases, involvement goes well beyond grain science, but grains are a significant part of their broader scope.

The American Society of Agronomy, the Crop Science Society of America and the Soil Science Society of America attract scientists involved in plant growth and production. While their interests include grain

production, the involvement of these societies covers the full breadth of plant-based agriculture. Complementary to this aspect of grain science is the International Seed Testing Association (ISTA), concerned with the earliest stage of plant production, namely, the provision of pure seed. Again, the scope of this society extends well beyond food grains to cover all types of plant seeds.

The American Association of Cereal Chemists

The AACC is an international non-profit organization of ~3500 grain scientists and other professionals studying the chemistry of grains and their products or working in related fields. The word "cereal," used in the name of this and some other societies, is now less appropriate than the term "grain." Long ago, the scope may have been restricted to the cereal species, particularly wheat and barley, but the broad range of grains is now included in the activities of these societies.

The AACC was founded in 1915 for the purpose of standardizing methods of analysis among cereal laboratories. The association now provides a comprehensive and respected collection of methods in the field of grain science (*see* **Appendix**: Test Methods for Grain and Grain-Based Products). All methods must meet rigorous standards for approval by one of AACC's 23 technical committees, which are composed of scientists chosen for their specific area of expertise.

The Activities of AACC Members

Many AACC members are involved in food manufacture using grains, one of the fastest growing, most dynamic segments of the food industry. They are responsible for producing some of the most popular and profitable products, such as new types of cracker, cookies, pretzels, or other snack foods. Bringing such products into the market involves designing, developing, and marketing skills. Breads, tortillas, frozen doughs, and dry mixes all rely on cereal chemists for their success in the marketplace.

Other AACC members are involved "upstream" of the food industry. They may be associated with plant-breeding programs, with responsibility for ensuring that the grain from new varieties is suited for specific marketing and processing requirements. Research activities are prominent for other cereal chemists, with the objectives of elucidating the chemical and molecular bases of grain quality, thereby laying a foundation for the development of improved testing methods for grain quality. Other research activities are likely to lead to the development of new grain types with better processing and nutritional attributes.

AACC Resources

The AACC has provided resources in grain science for more than 85 years, supporting members' professional needs in private industry, academia, and government. The association provides an avenue of bringing together scientific information and technical research on cereal grains and related materials, their processing and utilization. This information is made available through outlets such as annual meetings, seminars, training sessions, and in publications. The range of published materials includes scientific journals, books, and data provided on the website.

AACC publishes *Cereal Chemistry*, a journal with peer-reviewed, original research on raw materials, processes, and products that relate to the utilization of cereal grains, oilseeds, and pulses, as well as analytical procedures and methods in the grains area. AACC also publishes *Cereal Foods World*, which includes feature articles and original research that focus on advances in grain-based food science and the application of these advances on current practices in baking, snack foods, breakfast foods, and other grain-based products. In addition to these two journals, AACC has published more than 65 titles on various food-science topics. Some titles are technically focused while others are designed for generalists. The books in the AACC handbook series offer a single source of practical information for the major ingredients used in food processing.

AACC's website offers members the opportunity to obtain information and resources in one common location. The website features more than 40 years of searchable *Cereal Chemistry* abstracts, an online catalogue of books, special reports, membership listing, a calendar of events, and on-line symposia. AACC Interactive is the place on AACC's website where members can update their member record, register for the association events and purchase books.

AACC's continuing education programs offer professional development services for food-industry professionals at any level in a variety of food-related industries. Core services include short courses taught by experts that offer comprehensive training and real-world applications. These courses provide basic training tools for new associates or as a resource for anyone working with a new ingredient or application. AACC's continuing education programs also focus on emerging issues and strategies for the future success in the food industry. Members receive special rates on technically focused, hands-on training. Courses are offered globally.

AACC Meetings

The AACC's annual meeting is attended by an international audience of ~2000 grain-based professionals, providing an education and networking event for the grains industry around the world. At this meeting, presenters have the opportunity to share their latest research on topics such as biotechnology, functional foods and ingredients, health and nutrition, structure and function of food components, quality enhancements, and more. The annual meeting also features a tradeshow, typically comprised of more than 250 exhibits.

AACC members work together on various initiatives through AACC technical and administrative committees. Committee participants help identify emerging issues, create definitions for critical industry ingredients, as well as investigating and developing analytical methodology. Members with appropriate expertise comment via AACC management on items of public interest, such as the definition of dietary fiber and the value of foods based on genetically modified crops.

Members have the opportunity to attend local section meetings, connecting them to other professionals within their own region. The AACC also conducts regional meetings, such as the series of Pacific Rim Meetings for delegates from countries bordering the Pacific Ocean. Several divisions within the AACC cover specialist interests, such as grain proteins and biotechnology, and these divisions arrange seminars focusing on these interests. Under the guidance of the International Executive Council, AACC also responds to the needs of its international membership working in more than 75 countries. AACC's European office, located in Belgium, is staffed with bilingual professionals, providing support and services to members throughout Europe and surrounding countries.

AACC recognizes excellence through its awards program. AACC awards include the Geddes Memorial Award, the Thomas Burr Osborne Medal, the C.W. Brabender Award, the Excellence in Teaching Award, AACC Fellowships, the Alsberg-French-Schoch Memorial Lectureship, and Honorary Memberships. In addition, the AACC Foundation provides scholarships and fellowships annually for students majoring in disciplines related to cereal science.

The International Association for Cereal Science and Technology

The ICC was founded in 1955 on the occasion of the Third International Bread Congress in Hamburg, Germany, as the "International Association for Cereal Chemistry," with the initials ICC, which have remained, despite the subsequent expansion of its title (above). The original objective was the development of internationally approved and accepted standard testing procedures for cereals and flour. The scope of the ICC has since expanded to include international cooperation and the dissemination of up-to-date knowledge. The Association has its headquarters and its Secretariat-General near Vienna, Austria. More than fifty countries are represented in the ICC.

ICC Objectives

The ICC is a non-political, nonprofit-making organization. Membership is open to all interested countries that are prepared to offer their cooperation. The principal tasks of the Association are:

- to contribute to the advancement of cereal science and technology in all its aspects;
- to standardize test methods in cereal science and technology as well as in related fields; and
- to relate the results of scientific and technological research to the more efficient utilization of cereals.

ICC has the following special emphases:

- Cooperation with developing countries. ICC activities have involved the promotion and implementation of scientific and technical cooperation among and with developing countries through ICC regions in Asia, Africa, and South America.
- Cooperation with other international organizations. ICC activities so far have resulted in the conclusion of cooperation agreements with organizations working in similar or related fields.

ICC Organization and Activities

ICC is unique in that it does not provide membership to individual scientists. Instead it has country memberships (either Regular or Observer Country Membership). The ICC also has Corporate Membership, involving companies involved in the grain industry. ICC affairs are financed via fees paid by Country and Corporate Members. The ICC is governed by its Executive Committee, Subcommittee, and Technical Committee, supported by the Secretariat General and Chief Executive Officer, based in Vienna.

Many of the ICC's activities are carried out by some 40 Working and Study Groups, each of which is chaired by an expert qualified in the specific field of activity. Participation in the work of these groups is open to all qualified persons and guided by a Technical Director. Congresses and symposia, which ICC holds at regular intervals, offer opportunities for a direct exchange of views about developments and progress

in the various disciplines, and the reports about these meetings help disseminate the most recent findings.

ICC information is also disseminated via its website and via many publications, including *Standard Methods*, a newsletter, a multilingual dictionary, a book about people in Cereal Science titled *Who is Who in the World of Cereal Science*, a calendar of events and literature about ICC meetings.

National Cereal Chemistry Societies

Chinese Cereals and Oils Association

The CCOA, based in Beijing, China, provides opportunities of interaction for a large number of Chinese scientists working with grains, edible oils, and related commodities. Whilst its activities are mainly centered within China, the Association also hosts international conferences, thereby involving the wider range of grain scientists. The CCOA has over 6000 personal members and has over 570 organization members. The CCOA is a member of the ICC. The CCOA is divided into four sub-associations, namely, grain storage, grain food, edible-oil processing, and animal-feed production. The CCOA publishes a journal, the *Journal of the Chinese Cereals and Oils Association*. The Chinese version is published every two months, while the English version appears annually.

Australian Cereal Chemists

The Cereal Chemistry Division of the Royal Australian Chemical Institute (RACI), based in Melbourne, Australia, is a focus for grain scientists in Australia to meet in annual meetings, to exchange information and to interact with colleagues internationally. The Cereal Chemistry Division was one of the first specialist groups to form within the broader range of chemists of the RACI. From these beginnings early in the 1950s, the Cereal Chemistry Division has been one of the strongest of the various specialist divisions of the RACI, with a current mailing list of over 300 scientists. Attendances at Annual Meetings average $\sim$150. At regular intervals, these meetings are combined with other international societies, especially the AACC and the ICC. Other activities include conducting workshops and training seminars on specific aspects of grain science, the provision of standard methods of analysis, and facilities for checking samples with known analytical results by which laboratories are able to compare the results of their analytical methods with others.

Throughout the life of the Cereal Chemistry Division, presentations at annual meetings have been recorded in published form, in recent years under the titles *Cereals 2003*, *Cereals 2002*, *Cereals 2001*, etc. Details of these publications and other activities are provided on the website.

Societies Involved with Grain Growth

The International Seed Testing Association

The ISTA is a worldwide, nonprofit association, whose main activity is to provide methods and services for the testing of seed traded internationally. The primary purpose of the Association is thus to develop, adopt, and publicize standard methods for sampling and testing seeds of all types, not only the edible grains. The ISTA's secondary purpose is to promote all areas of seed science and technology. These purposes are largely served by the publication of relevant handbooks and bulletins, scientific journals (*Seed Science and Technology* and *Seed Symposium Abstracts*), Proceedings of Symposia and Workshops, and training booklets.

The primary ISTA "instrument" for promoting uniformity of seed testing procedures is *The International Rules for Seed Testing*, a publication that is updated annually with amendments and additions resulting from ISTA Meetings. This publication is available in several languages, including English, German, and French. The ISTA Secretariat is based in Bassersdorf, Switzerland. Details of publications and membership are available on the ISTA website.

The American Societies of Agronomy, Crop, and Soil Science

Founded in 1907, the American Society of Agronomy is "dedicated to the development of agriculture enabled by science, in harmony with environmental and human values." The Society supports scientific, educational, and professional activities to enhance communication and technology transfer among agronomists and those in related disciplines on topics of local, regional, national, and international significance. The Society's secretariat is in Madison, Wisconsin, USA.

The Crop Science Society of America is an educational and scientific organization comprised of more than 4700 members dedicated to the advancement of crop science. Founded in 1955, the Society is international in scope with members in more than 100 countries who are advancing the discipline of crop science by acquiring and disseminating information about crops in relation to genetics and plant breeding, crop physiology and production, germplasm resources, and environmental quality. An important function of the society is the production of its main journal *Crop Science*.

The Soil Science Society of America is the professional home for over 5700 professionals throughout the world involved in soil science. The primary purpose of the Society is to advance the discipline and practice of soil science by study and education concerning soils in relation to crop production, environmental quality, ecosystem sustainability, bioremediation, waste management and recycling, and wise land use.

Societies Involved with Grain Analysis

AOAC International

AOAC International is an internationally recognized organization with 120 years of experience in validating and approving analytical methods for foods and agriculture. It is "committed to be a proactive, worldwide provider and facilitator in the development, use, and harmonization of validated analytical methods and laboratory quality assurance programs and services."

The organization was founded in 1884 as the Association of Official Agricultural Chemists, under the auspices of the US Department of Agriculture. Its initial role was to adopt uniform methods of analysis for fertilizers. In the following year, a Convention established the AOAC as an independent organization, but membership was restricted to analytical chemists in state and federal positions of the US government, and this membership requirement remained for ~100 years. In 1965, to recognize the expansion of AOAC's scope of interest beyond agricultural topics, the Association's name was changed to the Association of Official Analytical Chemists.

During the 1970s, membership was extended to scientists outside the United States, and to nongovernmental scientists. Now over 60% of members are working in industrial laboratories. During the 1980s and 1990s, the scope of analyses expanded and there was increasing demand for quality control of laboratories and international laboratory accreditation. Consequently, the name of the Association was changed to AOAC International, thereby retaining the initials by which the Association had been known for over 100 years, while eliminating reference to a specific scientific discipline or profession.

The scope of the AOAC includes not only methods for the analysis of grains, but also for a much wider range of materials. AOAC provides a number of key publications, hosts technical meetings and conferences, and offers training courses in the areas of laboratory management, quality assurance, accreditation, statistics, and measurement uncertainty. Information is readily accessed at the website.

The American Oil Chemists' Society

The AOCS is another American scientific association that has become international, growing and expanding in scope since its origins in 1915. This scope now includes oil- and fat-related commodities, oilseeds, oilseed meals and edible fats. Grains are thus prominent in this range of materials for analysis, but the scope goes beyond grains, including other sources of edible fats, such as fish and animals. The AOAC technical services are based in Champaign, IL, USA.

Celiac Societies

Societies have been formed in many countries and regions by people with celiac disease and related forms of dietary intolerance to gluten (*see* **Celiac Disease**). These are not associations of scientists, but rather of people with celiac disease, together with their relatives and friends. They may, in turn, rely on scientists and medical workers to provide advice in the forms of publications, consultation, and conference presentations for the benefit of the members. A few web addresses are provided in the list below, but there are many more such societies worldwide.

SNACK FOODS, PROCESSING

M N Riaz, Texas A&M University, College Station, TX, USA

This article deals with different aspects of snack food production. It covers the areas of snacking patterns, types of snacks, raw material for snack foods, and different snack food manufacturing details. This is intended to be useful for the snack food industry as well as for marketing professionals to understand different types of snack and trends, and for consumers who wish to gain more knowledge about snacks.

Background

Snack foods have always been a significant part of modern life; they represent a distinct and constantly widening and changing group of food items. Sales in 2000 were over $19.37 billion and per capita snack consumption was 10 kg. According to a rough working estimate, annual worldwide sales including the US was $30–35 billion. American Heritage dictionary defines snack as "hurried or light meal" or "food eaten between meals." Traditional snack foods appeal to consumers on a number of levels. Snacks can be considered a treat or reward. Designing snack foods today can be a complex process to meet changing consumer's taste and expectation, e.g., "good for your health," "rich source of soy protein," "offering a unique flavor," and the elusive search for something unique that also appeals to a wide variety of people. Most snack manufacturers use some form of existing technology as the basis for creating snack products, but incorporate variations that increase the resulting snack's health image appeal by lowering fat and calories or adding nutrients.

Snack Consumption Patterns

The snack food market is constantly changing relative to product types, and although most snacks are not primarily consumed for their nutrients, many snacks are made with nutrition in mind. The snack food industry is experiencing extraordinary changes from the consumers' point of view. Consumers want snacks to not only taste good, but also smell good, feel good, and look good. Snacks should give the consumer a homemade/fresh feel. Some of the snacks are developed with a special theme in mind like world soccer. These snack pellets are soccer ball shaped, which on

Figure 1 Different shaped snacks.

frying or treating in a microwave oven become soccer balls (Figure 1).

Snacking is increasing from factors such as increases in one-person households, higher proportions of working spouses and more school age children obtaining their own meals and refreshments, a highly mobile population, and availability of snack foods in vending machines and convenience markets. Various products, which were once consumed mainly on impulse, are becoming accepted as side-dish items, for example, corn chips or potato chips served in place of mashed potatoes. The established position of snack foods in the diet is demonstrated by the continuous growth in sales.

In the last ten years, changes in lifestyle and eating patterns have led to a gradual increase in demand for snack foods. The pattern of snacking in different countries can be affected by several factors such as the lifestyle in each area, the economic climate, rival foods, and public receptiveness of current views on nutritional matters. Snacks can provide an increased dietary intake of essential amino acids and other nutrients for developing countries.

Some of the most recent factors driving the newer snack food trends are – (1) availability of healthy snacks like energy bars or soy fortified bars, (2) better taste and flavors, (3) better and attractive shapes for children and packaging, and (4) better varieties of snacks like soy nuts or yogurt bars, etc.

Types of Snack Foods

Although it is not possible to discuss all types of snack foods available in the market in this article, only major types of snack foods like potato chips, corn and tortilla chips, and extruded snacks (expanded and pellets snacks) will be discussed in detail. A broad variety of snacks made by different processes

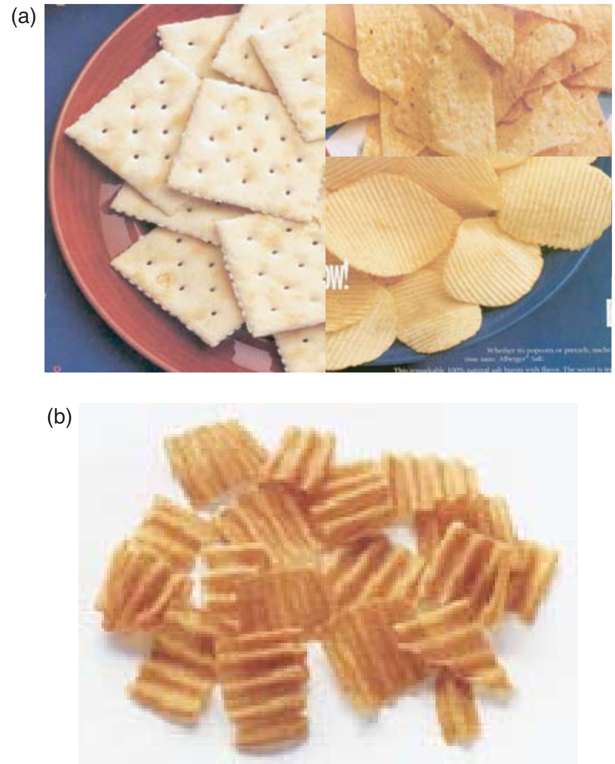

Figure 2 (a) First generation snacks. (b) Multi-grain chips.

are available in the market. These include potato chips, tortilla chips, corn chips, ready-to-eat popcorn, extruded snacks, pretzels, snack nuts, meat snacks, pork rinds, party mix, multigrain chips, granola products, variety packs, etc. Most recently, a variety of health snacks made with soy protein have been seen. These soy-based snacks contain 6.25 g of soy protein per serving to qualify for the health claim of the Food and Drug Administration. Along the same line, snacking on soy nuts is becoming very popular among the health-conscious consumers. Nowadays, soy nuts can be found with different flavors in most grocery stores. Snacks with different spices and flavors are becoming very popular with US consumers. There is a substantial growth in ethnic snacks from Mexico and India in the markets. Snacks from India are mostly fried lentils and chickpeas, and similar types of pulses with different flavors (mostly with chilli powder) are entering the US market.

Each snack processor may use a specific unit operation and somewhat different technologies to produce unique snacks. There are many ways to classify the snacks. Snack manufacturers use three main terms to identify the snacks (see Figures 2–4):

1. *First generation snacks*. In this category all the natural products used for snacking, nuts, potato chips, and popped popcorn are included;

2. *Second generation snacks*. Majority of the snacks fall in this category. All the single ingredient snacks, simple-shaped products like corn tortilla chips and puffed corn curls and all directly expanded snacks are included in this category;
3. *Third generation snacks (also called half-products or pellets)*. In this category, snacks and pellets

Figure 3 Second generation snacks.

Figure 4 (a–d) Third generation snacks. (e) Example of co-extruded snacks. (Courtesy of Wenger Manufacturing, Sabetha, KS.)

formed using multi-ingredients, made by extrusion cooking are included.

Production of Snacks

It is not possible to discuss every snack-manufacturing procedure in detail (see Figure 5). Manufacturing of only major snacks will be discussed here.

Potato Chips

The potato chips form the largest snack food sector in all markets. Traditional potato chips start with whole, raw potatoes sliced from between 0.035 and 0.070 inches thick. These cuts can be straight, grooved, crinkled, or flat surface. The most important point is that slice surface should be uniform for all these cuts. These slices are washed with water to remove starch and eliminate sticking, or can be blanched to reduce the level of reducing sugars to avoid browning before frying. The critical parameters for the chipping potatoes are moisture, starch, and sugar level. For a good potato chip, the dry matter should be ~20–23%, giving a specific gravity of 1.080–1.095. Potatoes with a lower specific gravity require a longer frying time and absorb more oil.

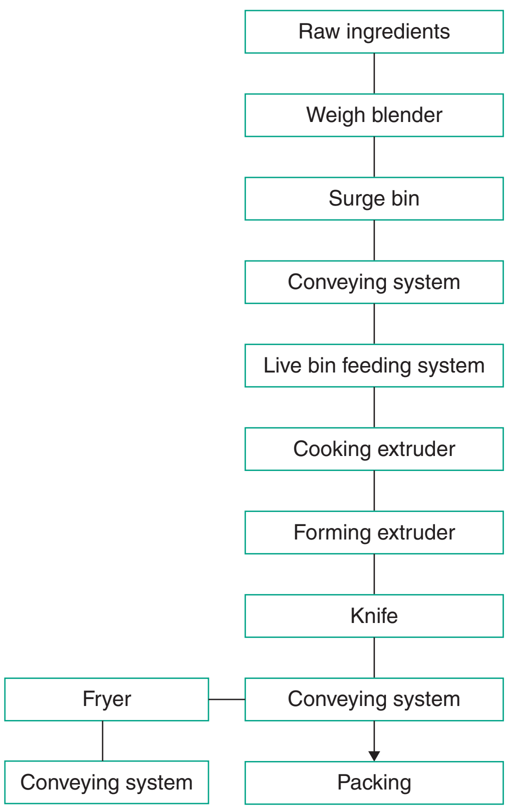

Figure 5 Third generation snack-manufacturing procedure.

In general, potatoes contain 80–85% water, depending on variety. The rest is (15–20%) dry matter, which is ~90% carbohydrates, mainly starch. The major concern with the carbohydrates portion is reducing sugars. The sugar contents may be as high as 10% of the dry matter. However, for potato chip processors, a sugar level above 2% is a concern as it induces the Maillard reaction during frying and makes unacceptable dark color potato chips.

Potato chips can be fried using batch or kettle frying or continuous frying. In batch operation, chips have a higher fat level, more blistering, and a harder surface due to the presence of starch on the surface. Whereas with a continuous fryer, the potato slices are continuously fed into the fryer, and cooked as they are conveyed and removed at the end. After frying, before the product cools and the surface oil solidifies, the chips receive an application of salts and or seasoning. Typical salt levels are from 1.5% to 2.5% and the seasoning levels range from 4% to 8%. The typical potato chip has a fat content of 35–40% making it difficult for most consumers to categorize it as a health snack.

Corn and Tortilla Chips

The increased popularity of certain ethnic snacks, such as corn and tortilla chips, has significantly increased this segment of the snack food industry. These snacks are very popular in South America. In recent years, their visibility has increased in North America also. After potato chips, corn and tortilla chips represent the second largest category of salted snacks. The main difference between tortilla chips and corn chips is the extra baking step required in the manufacture of tortilla chips.

The key to the process is initial nixtamalization or alkaline cooking and steeping step involving whole corn. In the past, not much attention was given to corn type in the manufacturing of fresh “masa” that was to be immediately converted to chip products. However, corn quality is quite critical in the manufacture of dry masa. In the actual process, good quality whole corn is cooked for up to 3 h at 80–100°C with frequent stirring in 120–300% excess water containing 0.1–2.0% hydrated lime. The cooked corn is then permitted to steep, usually overnight. The cooking and steeping steps permit the endosperm to hydrate and soften, which encourages partial starch geletinization, and disrupts and partially dissolves the pericarp. Subsequent washing removes the pericarp and residual lime. The resulting cooking/steeping liquor normally contains 2–6% dissolved and suspended solids, which are usually discarded. The washed material is then traditionally stone ground, resulting in fresh masa, which is then

sheeted, cut, and either baked and fried to produce tortilla chips or just fried after sheeting and cutting to make corn chips. In the case of corn chips, the masa can be directly extruded and cut into the frying oil instead of being sheeted and cut.

If reconstituted masa flour is used, a large particle size should be used for corn chips. This will provide for interruption in the dough structure so that air and water can escape during frying. If small particle flour is used, excessive puffing occurs during frying, resulting in a chip that will absorb more oil during frying and can be easily broken. On an average basis, corn chips contain 35% fat, whereas good quality tortilla chips have 25% fat. This is because of the preliminary baking step with tortilla chips, which set the structure, therefore minimizing the oil absorption during frying. Usually, corn chips are made with a blend of white and yellow corn masa, which produces chips that are light in color. Corn chips made from 100% yellow corn masa usually have an objectionable burnt flavor, which can be attributed to the degradation of carotenoids during the frying step. Flavors and colors can either be added to the dough, which can result in significant flavor loss due to volatilization or degradation during frying, or they can be added either as a powder or in the form of an oil spray after frying.

The traditional corn cooking techniques to prepare masa or corn/tortilla chips are being changed by more efficient, large scale operations where corn is cooked and ground immediately with little or no steeping. New and simple methods of producing corn and tortilla chips, and other masa-based snacks have been developed. Many snack food manufacturers like to use dry masa flours that come in a variety of color and particle sizes. By adding water in precooked masa flour, different shapes of snacks can be made by using a forming extruder. These snacks can be fried, flavored, and packaged for sale. Frying has increased the masa-based snacks market, because after frying, the final product has an excellent taste and texture and a long shelf life. Typical flow diagrams of tortilla and corn chips production are shown in Figures 6 and 7.

Extruded Snacks

This category has the greatest potential for growth among the snack foods. The snacks can be produced using innovative methods (see, e.g., Figures 8–10) which capture the consumer imagination. Some of the examples are three-dimensional snacks, a variety of animals, cartoon, and alphabets shapes etc. Producing a successful snack is a fine balance between the consumer's needs, like tastes and interests versus a manufacturer's production abilities, economics, and quality control. Raw material cost plays an important role in the finished product's selling price. Therefore, it is an advantage to use the lowest cost raw material to produce a successful snack.

Common ingredients used for extruded snacks Presently, snack products are being made from a variety of ingredients (see Table 1 where typical properties of common raw materials are listed). However, the selection of the ingredients was limited by the equipment availability. The introduction of the

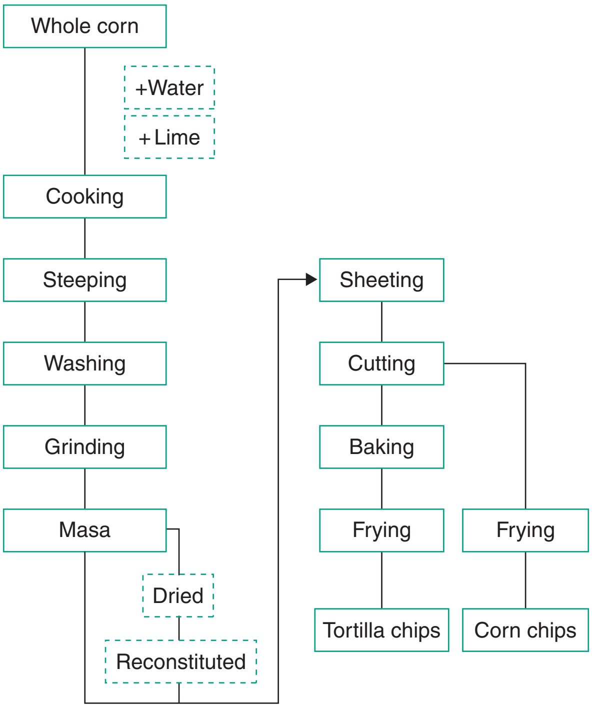

Figure 6 Flow diagram of tortilla and corn chips.

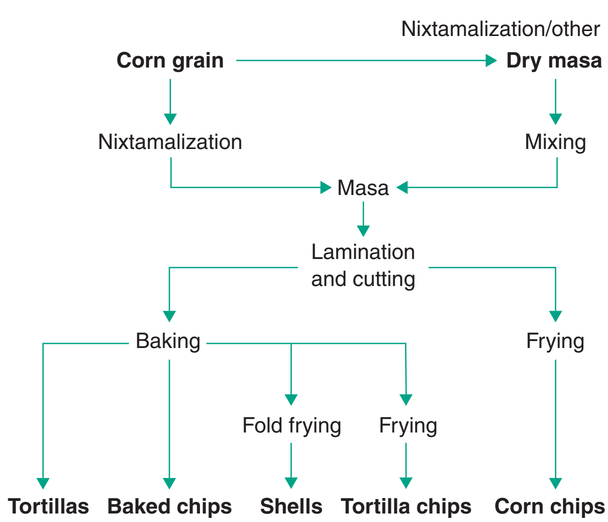

Figure 7 Corn and tortilla chips production.

extrusion process, other processing equipments, and better knowledge of extrusion technology have led to more diverse and complex formulations for snack foods. The most common source of ingredients are corn, wheat, rice, potato, tapioca, and oats. This is not an inclusive list and one should not limit his/her snack food formulation based on these ingredients. There are several other sources of ingredients for snack food all over the world. A major ingredient in snack food formulation is starch. In its natural form, the starch is insoluble, tasteless, and unsuited for human use. To make it digestible and acceptable, it must be cooked.

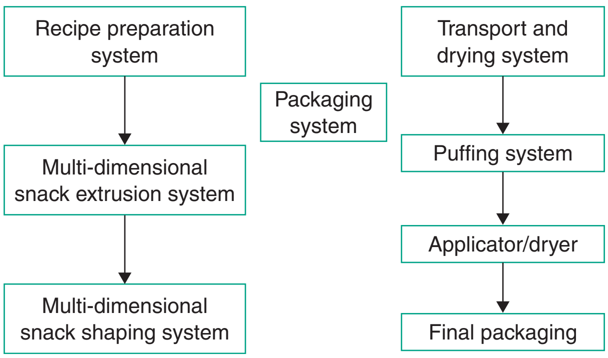

Figure 8 Multi-dimensional snack production.

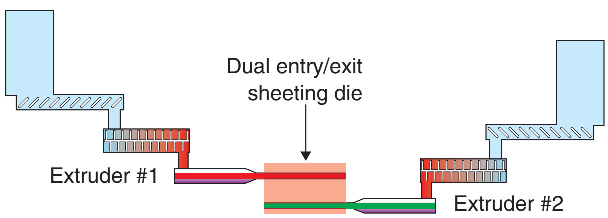

Figure 9 Multi-dimensional snack extrusion system.

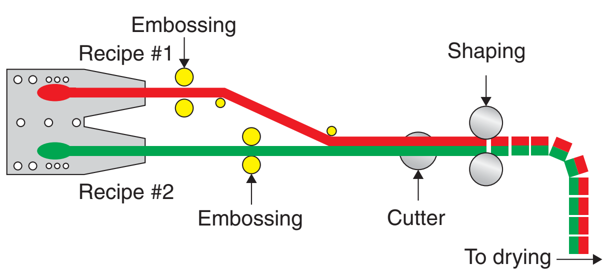

Figure 10 Multi-dimensional snack shaping system.

Table 1 Properties of different raw material in relation to snack food production

Raw material	*Granule size (μm)*	*Flavor*	*Expansion*	*Texture*
Corn	5–20	Definite	Very good	Crispy
Wheat	20–40	Mild	Good	Crispy
Rice	2–8	Bland	Good	Crispy
Oats	2–12	Very strong	Poor	Soft to hard
Barley	Medium to large	Mild	Poor–good	Soft to hard
Potato	60–100	Definite	Very good	Crispy
Tapioca	5–35	Bland	Good	Crispy

Cereal sources Almost any cereal can be extruded, but if expansion is a major objective, the numbers of functional cereals are limited to de-germed corn/grits and rice. Cereals that have high amounts of lipids are more difficult to expand due to dough slippage within the extruder barrel. This type of cereal usually requires high moisture and high temperature before significant puffing can occur. In general, starches with 5–20% amylose content will significantly improve expansion as well as texture of the snack foods. The most common cereals used in snack food formulations are described below.

Corn Extruded snacks are a growing segment of the corn-based market (see Figure 11). Corn (also called maize) is a primary ingredient for corn collets and many pellet products. For most corn-based extruded snacks, dry-milled corn meal is used. Large quantities of corn meal are used in puffed extruded snack production and some are used in corn chips. Corn meal, corn grits, corn flour, and corn cones are all a different form of dry-milled dent corn, and in general vary only in particle size distribution. Selection of the granulation depends upon the type of snack and type of extruder. For example, for fine texture and cell structure, or softer bite, a fine granulation of corn meal should be

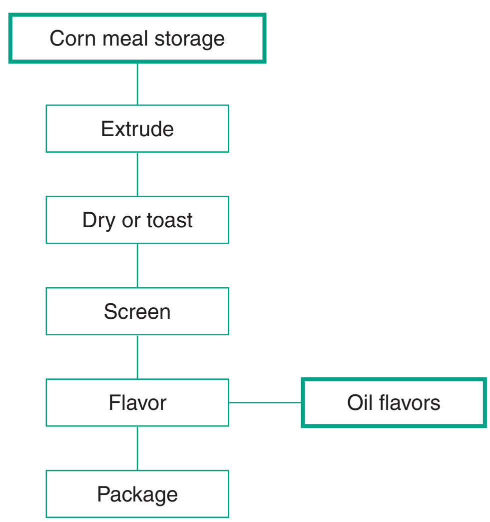

Figure 11 Flow diagram of baked collets.

used. Whereas for crunchy texture with a slightly larger cell structured snack, a more coarse granulation of corn meal is desired. Similarly, a twin screw extruder can handle fine as well as coarse granulation corn flour, while collect extruders require coarse granulation. Mostly, de-germed corn is used in extruded snacks because it expand better than whole corn. Yellow and white corn are most commonly used in snack foods. Cornstarch granules are medium in size (5–20 μm) and have very good expansion characteristics. Protein content of corn ranges from 6–10%. Snack food formulations with corn have a definite flavor. Cornstarch is usually cooked at a medium to higher temperature during extrusion. The function of the starch in snack foods is to achieve various textural attributes and characteristics. Changing the amylose/amylopectin ratio in the starch can change these attributes. Today, we can find cornstarches with high amylose or high amylopectin in the market. High amylose cornstarches are used when crunchiness and strength is required in the snack. To increase the expansion of the snack, high amylopectin cornstarches (waxy starch) can be used. Waxy corn contains very little amylose, whereas the normal corn contains ~25–35% amylose. Under high shear and high temperature cooking, a cross-linked waxy cornstarch is recommended in snack foods, since it exhibits an improved property of resistance to amylopectin breakdown.

Wheat In general, wheat can be classified into two types: hard and soft. Hard wheat is higher in protein, produces stronger flour, and is better for bread making. On the other hand, soft wheat is lower in protein, yields weaker flour, which is better for cake making. In the snack food industry, wheat flour is used in formulation for making baked and fried snacks, flavored crackers, snack cakes, pretzels, bread, and the like. Semolina, (coarse particle) usually produced from hard wheat milling, is also used in snack food formulation. The semolina product has an expansion ratio and bulk density about the same as corn meal. Snack foods with all-semolina will produce a very crispy texture. Wheat starch granules are fairly large (20–40 μm) as compared to other cereal grain starches. In wheat, amylose and amylopectin are found within a narrow range of 20–25% amylose. It gives good expansion during extrusion cooking. Wheat is relatively higher (8–15%) in protein than other cereals. Sometimes it is difficult to expand due to the presence of gluten. In extruded snacks, wheat gluten provides nutritional value, crispness, and desired texture. In general, 1–2% wheat gluten is used in snack foods. Hard wheat is commonly used in bread rolls, pretzels, and fabricated or pellet type snacks. Wheat varieties with a lower gluten level, give a more tender expanded product than semolina, or hard varieties. Snack products made with wheat usually have mild flavor and white to off-white color. It needs medium to low cooking temperature during extrusion cooking. Milling by-products (bran) can be used with soy protein and some other ingredients to produce expanded snack foods of high nutritional and fiber value. The use of wheat in snack food formulation is limited because of cost.

Rice Rice is one of the largest crops grown in the world. Four types of rice are produced in the United States: long, medium, short, and waxy grain. In the US, rice ingredients are not commonly used in snack food formulation. In Japan, most of the snacks are made with rice or rice flour. One major reason is the cost of rice as compared to that of other snack food ingredients. Broken rice can be used as ingredient in expanded or puffed snack products, since rice has good expansion qualities. Rice starch granules are the smallest (2–8 μm) of all grain starches and can digest very easily. Its functional properties are very different from corn or wheat starches. The primary difference is in amylose/amylopectin ratio in the starch. Flours from different rice varieties have major differences in physical and chemical properties, which can affect the snack cell structure and expansion. For example, long grain rice flour can increase the crispiness in snack foods, whereas waxy rice flour can reduce chip hardness and at the same time can provide a melt-in-the-mouth texture usually achieved with extra fat. Rice is commonly used as a carrier product for other flavors, since it is bland in flavor. In comparison with other products, rice requires the highest temperature during extrusion to cook a snack. Selection of the rice starch in the snack foods formulation will depend upon the amylose content of the common rice varieties. Long grains have 22–23%, medium grain 15–19%, and waxy grain $<1\%$ amylose. This difference in amylose/amylopectin ratio greatly affects the gelatinization temperature of rice flour. The protein content of rice ranges from 6% to 8%. Rice flour could be used for texture improvement in multi-grain snack foods. Rice flour can be mixed with masa flour, potato flakes, or bean flakes. Chips made with 100% rice flour absorb 20–30% less oil during frying. In a formulation where rice and potato blend is used, the potato flavor and texture remains distinctive even though it is mixed with the less costly rice blend. A mixture of bean flake and rice flour produces a distinct visual appearance of the beans while creating a well-blended bean flavor with no bitter aftertaste.

Oats In general, oats are marketed as rolled oats or as an ingredient for breakfast cereal. Oats have not been used in grain-based snacks as wheat and corn. Recent discoveries, that oat bran can reduce serum cholesterol level in humans, have boosted the market for oats in the snack food industry. The major problem with oats is high oil content (7–9%) and lipase enzyme. Before using oats in the snack food formulation, it is desirable to inactivate the lipase. Otherwise, lipase will catalyze the hydrolysis of oil, which would lead to the production of bitter tasting free fatty acid. Oat starch granules are comparatively small (2–12 μm) in size as compared to other starches. Amylose content of oats varies from 16% to 27%. Oat starch has a very strong flavor and it gives light brown color to the product. It requires a relatively low gelatinization temperature, but a higher amount of energy input for cooking because of higher amounts of oil content. Oats contain high levels of fiber. Snacks extruded with oat starch expand poorly. For this reason, it has only found its way into products at low levels. By using longer barrel extruders with preconditioner, a higher level of oats can be used in snack foods. Among the snacks that have traditionally included oats in their formulation are cookies and granola. With new technologies and more interest in oats due to health claims, oat-based snack products may be popular in the future.

Barley Barley is used in small quantities in some snack food formulations. It has a mild flavor, and nutritionally, it is almost the same as wheat, except it contains considerably more fiber. Barley starch granules are medium to large in size as compared to other cereals. A reasonable amount of expansion can be obtained during extrusion of snack foods using barley starch. It gives a light brown to gold color to the product. Snack food formulation containing barley starch needs a low cooking temperature during extrusion. Barley fiber can be used in healthy snack foods as a fiber supplement. Sometimes, manufacturers use barley in multigrain snack foods in order to add one extra cereal on the label.

Other cereal sources Cereals such as rye, sorghum, millet, amaranth, and triticale have been used in snack foods. Presently, these cereals are not major ingredients in the snack food formulation.

Tuber sources Roots and tubers belong to the class of foods that basically provide energy in the human diet in the form of carbohydrates. According to a recent estimate by Food and Agriculture Organization (FAO), virtually every country in the world grows some species of root crop. Potato and tapioca (also called cassava) are two main tuber crops used for extruded snack foods.

Potato Different forms of potatoes (granules, flakes, flours, and starches) are used in snack food formulations. Potato starch is often used in snacks to provide extra expansion. Potato starch has a wide range of sizes with some granules (60–100 μm) larger than the other cereals. This starch contains 20–25% amylose and has very low oil contents. Potato starch develops high viscosity during extrusion cooking. It has an excellent swelling and binding power. In snack food, it has a definite flavor and it gives gold to light brown color to the product. It requires low cooking temperature since its granules breakdown easily. Potato flour is the major ingredient for two common snack products, i.e., direct expanded snack (product looks like French fries) and fabricated chips.

Tapioca Tapioca (cassava) is a basic source of low calories, or a supplement to cereal. In general, tapioca starch is used in third generation snack foods formulation. Tapioca starch grains vary in shape, and size from 5 to 35 μm. The amylose content is ~17%. Good quality starch should have a pH of 4.7–5.3, a moisture content of 10–13.5%, and should be uniformly white in color. Tapioca starch develops a very high viscosity and it is an excellent binder. It has a bland flavor and requires moderate cooking temperature during extrusion cooking.

Expanded Snacks

The majority of extruded snacks are in this category. This group is also referred to as "collet" or "second generation snacks." In general, expanded snacks are made on high-shear extruders. These are high-fiber, high-protein, and low-calorie snacks. Some examples are corn curls, onion rings, three-dimensional snacks, and potato sticks. These types of snacks can be seasoned with a variety of different flavors, oils, salt, sugars, etc. The quality of an expansion-cooked product depends upon the conditions of operation of the extruder and the main raw material used in the formulation. Several other factors can influence the degree of puffing of snacks during extrusion, i.e., amount of moisture in the feed material, dough residence time in the extruder barrel, and cereal particle size.

Fried collets These are the most familiar extruded snacks in the market. A special die arrangement gives the product a twisted and puffed shape. These collets are made on collet extruders. The product is then fried in vegetable oil, and coated with cheese and some

other flavor. During frying, the moisture level reduces from 8% to 1–2% in this product. The most common material used for fried collet is corn meal. Typical corn meal specifications are given in Table 2. Some other cereal grains can also be used for this type of product.

Baked collets Baked collets are another example of the expanded extruded snacks. These include products such as baked corn curls, onion rings, and potato sticks. Baked collets can be made with different cereal grains and tuber flours. Protein, fibers, cellulose, and bran can be blended with cereal grain up to 20% to make healthy snacks. Potato sticks are usually made by mixing potato flour with corn or rice flour. A typical formulation for baked snacks is given in Table 3.

Third generation snacks Third generation snacks, also referred to as "half products" or pellets provide an alternative to fully prepared puffed snack foods. Third generation snacks, or half products are extrusion cooked, and formed at low pressure to prevent expansion, and then dried to a final moisture content of ~10% to form a glassy pellet. In developing third generation snacks, "half" of the process is completed to prepare "pellets" which are shelf-stable for periods of up to a year without refrigeration, provided they are properly packed to retain their moisture. These products are economical to run and have built-in-marketability due to their high-bulk density. Third generation snacks can be prepared in homes or restaurants. Unlike typical snack foods, half-products do not yet contain oil that can oxidize to give off-flavor to the products. These pellets can be shipped from a central manufacturing distribution point, held until needed for the market, and then puffed, flavored and packed fresh and locally. New variations of the third generation snacks expand using infrared heating, hot air, or microwaving. The use of hot air systems reduces the oil uptake that occurs in frying and allows a controlled addition of oil to be made as required for flavoring. With consumer concerns about fats and oils, a half product snack that expands using hot air, offers snack food manufacturers an oil free snack with perceived health benefits. Elimination of frying oils reduces calories and allows a marketing opening for snacks with a "lite" image. A typical flow diagram for the production of third generation snacks is shown in Figure 12.

With the multidimensional snack system, a wide range of raw ingredients can be used to blend together to make an excellent formulation for many types of third generation snacks. The extruder feed must contain a high level of starch to maximize expansion of the collet during exposure to hot oil or air. Levels of 60% or less total starch in the formula give only slight expansion in the puffing step and yield a final product with a crunchy, hard texture. Wheat, corn, and tubers are widely grown crops in developing and industrialized countries, and they are cheaper and more easily available in the market than other cereal crops. Several formulations for third generation snacks are given in Table 4.

Table 2 Typical corn meal specifications for fried collets

Granulation (mesh)	*Percent retained on screen*
16	0
20	0–2
25	0–10
30	25–50
40	45–65
50	0–8
60	0–2
Moisture	11–13%
Fat	<1%

Potato-stick snack	
Potato granules	64
Degermed corn meal	35
Vegetable oil	1
Corn curls	
De-germed corn meal or grits	100

Co-Extruded Snacks

This is a relatively new technology introduced in 1984 for the snack food industry. In this process, two different materials are extruded from one die. The two materials can come from two extruders or from one extruder and one pump. This process can produce a snack with two different flavors, or two textures or two colors. The most common snack produced by co-extrusion is a cereal based outer tube with a cheese filling inside. There are three basic types of co-extruded snacks in the market; cereal-based tubes with cereal-based fillings, cereal-based tubes with fat-based fillings, and cereal-based tubes

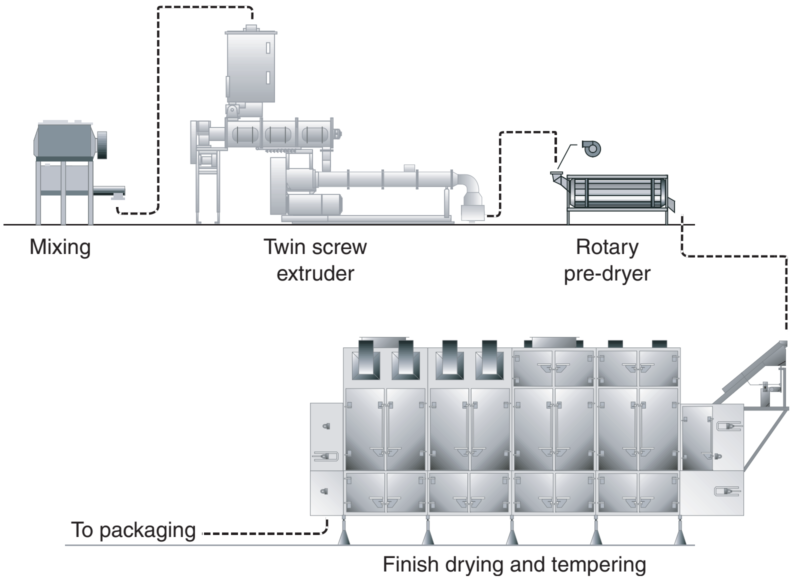

Figure 12 Flow diagram for third generation snacks.

Table 4 Typical third generation snack formulations

Ingredients	*Amount (%)*
Corn based	
Hard, crunchy texture	
Ground corn	94.5
Corn starch	5.0
Monoglyceride	0.5
Soft, frothy texture	
Corn starch	55.2

		Dairy powder	10
		Salt	2

with water-based filling. The shelf lives of these snacks are limited, because of migration of moisture and/or oil from the filling to the outer shell. A typical formulation of co-extruded snacks is given in Table 5.

In conclusion, snacks can be processed by a variety of different methods and techniques. Several new raw materials containing nutraceutical and functional properties are being introduced in the market every day for snack food products. Snacks can be made with a combination of different raw materials containing different properties. The role of snacks in a healthy life style is only now being developed. The recognition of snacks as healthy foods will increase as industry changes products from those having merely good tastes to nutritious ones.

SORGHUM

Contents

Breeding and Agronomy

A B Obilana, ICRISAT, Hyderabad, Andra Pradesh, India

Introduction

Sorghum breeding and agronomy as components of sorghum improvement have been the critical issues being addressed by scientists, educationists, researchers, producers, consumers, and other end users including industry and policy makers. The emphasis has been on increased productivity, adoption and sustained production, environmental and biodiversity management, and livelihoods of people in the semi-arid and drought-prone subhumid areas of the world. The present plateau in the production levels of sorghum across the globe and disenchantment of commercialization forces and agents, have all combined to generate continued interest in the improvement of sorghum through breeding and agronomy.

This article critically reviews the current state of knowledge of the topic and puts in perspective old and new breeding methods and tools. The article also pioneers the new paradigm of breeding for impact, highlighting the need for strategic collaboration and partnerships among stakeholders in generating new methods, tools, and improved products from breeding of sorghum. This is put in a scenario of traditional and classical breeding and agronomy

approaches as compared with nonconventional and applied breeding and agronomy.

General Description and Botany of Sorghum

Characteristics, Morphology, and Phenology

Sorghum is a single- to multi-culmed C4 plant with perfect flowers; grass species cultivated in diverse and adverse environments from subhumid, hot and dry agro-ecologies, to drought-prone low-to-medium altitudes of the tropics and subtropical regions of the world. This very versatile crop is truly multipurpose, and is used as: (1) grain for food, livestock feed, and industrial products like malt, alcoholic and nonalcoholic beverages, lager beer, stout, and malt drinks; (2) crop residue and silage for livestock feed; (3) chewing cane of the sweet stalk sorghums, (4) household appliances (in fencing and roofing with the dried stalks and as a broom for sweeping with the broomcorn types); and (5) sources of industrial alcohol and household brown sugar with the sweetstalk sorghums.

The sorghum plant is composed of two major sections: (1) the vegetative part consisting of the fibrous root system, the culm (stem), and leaves with leaf sheaths wrapping around the node and internode of the culm; and (2) the reproductive portion called inflorescence (panicle) carried on a peduncle (neck, which can be straight or curved (goose neck)) which can be well exerted (short or long neck) or poorly exerted with panicle partially covered by the boot (flag leaf and sheath). The peduncle extends into a central axis of the panicle called rachis, from the nodes of which several branches originate, which bear racemes. The racemes carry one or more spikelets (flarets), which bear the seeds subtended by glumes. Figure 1 shows the sorghum plant and its components.

The sorghum seed is a caryopsis composed of pericarp, endosperm, and embryo. Each of these consists of complex sections and constituents. The sorghum seed can be white, gray, red or brown in color, based on combination of pericarp color (which can be white or red only) and the presence or absence of testa (seedcoat which is always dark in color). The endosperm is always white and can be corneous (hard and translucent) or floury (soft and opaque). Thus, a seed having:

- white pericarp with no testa is described as having white seed color;
- white pericarp with testa is described as having gray seed color;
- red pericarp with no testa is described as having red seed color; and
- red pericarp with testa is described as having brown seed color.

There are several shades of red and brown seed color in sorghum due to expressivity and intensifier gene actions.

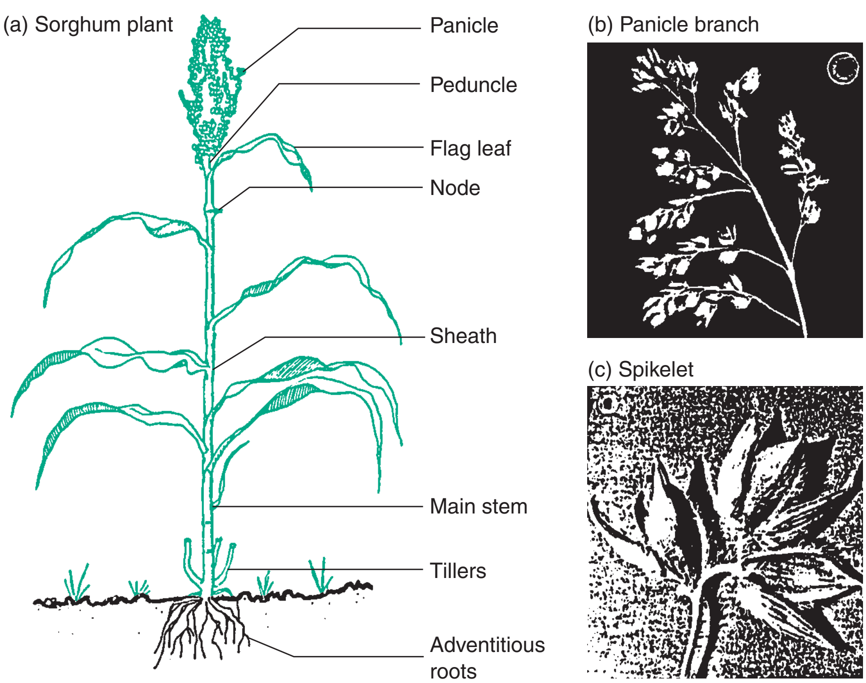

Figure 1 Diagram of the sorghum plant (a) and its components (b and c).

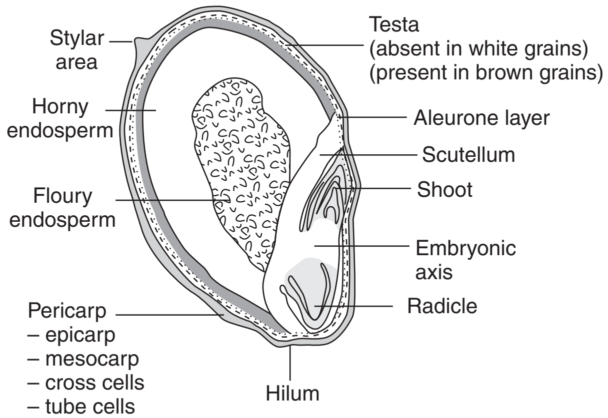

Figure 2 Longitudinal section through sorghum seed.

Figure 2 shows the longitudinal section through a mature sorghum seed. The pericarp is three-layered with epicarp, mesocarp, and endocarp of cross cells, tube cells, and aleurone cells. The aleurone layer cells could have been absorbed and absent, or in other circumstances, this layer persists and is present in mature seed as the testa. Below the pericarp is the corneous endosperm, which may surround (fully or partially) the inner floury endosperm. At the base of the seed, in an angle, is the scutellum (towards the endosperm) covering over the embryo. The embryo consists of the embryonic axis at the top of which is the shoot (develops into stem, leaves, and inflorescence) and at the bottom is the radicle (develops into roots). The physiologically mature seed has a dark hilum at the base, where it was connected to the ovary. The hilum consists of dried up transfer cells, placento-chalazal pod, and phloem parenchyma.

Biodiversity and Genetics

Sorghum biodiversity and genetic resources acquisition, maintenance, characterization, and utilization (curation) are the basis of breeding in the crop. Two organizations, International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) and International Sorghum and Millet Collaborative Research Support Program of USA (INTSORMIL), play global roles in the curation of sorghum. The diversity in sorghum is very unique and large in size. For example, ICRISAT has a collection of 35 643 accessions and the National Plant Germplasm System (NPGS) collections in the USA include 40 477 accessions of sorghum. These collections include both active (working collections) and base collections, which are preserved in medium-term conventional storage (about −18°C) and long-term cryo-storage (vapor phase above liquid nitrogen at about −160°C).

In the preserved germplasm accessions, the unique diversity of sorghum has been classified according to species. There are the cultivated sorghum (*Sorghum bicolor* L. Moench) and the wild weedy species. Within cultivated sorghums, there are five basic races (race guinea, race candatum, race durra, race bicolor, and race kafir) and ten stable hybrid races. The hybrid races are guinea-caudatum, guinea-durra, guinea-bicolor, guinea-kafir, candatum-bicolor, durra-candatum, dura-bicolor, kafir-candatum, kafir-bicolor, and kafir-dura. These 15 races of cultivated sorghum can be identified by a combination of seed (size, shape, plumpiness, and color) and glume characteristics (grain covering and glume color) with some help from panicle (inflorescence) traits. Among the wild and weedy sorghum, there are:

- *Sorghum halepense* (L.) Pers. ($2n=40$), a rhizomatous (perennial) autotetraploid species;
- *Sorghum almum* also a forage grass is autotetraploid ($2n=40$);
- *Sorghum propinquum* (Kunth) Hitchc. ($2n=20$);
- *Sorghum arundinaceum* (Desv.) Stapf. (Shattercane);
- *Sorghum aethiopicum* (Hack.) Roger. Ex Stopf;
- *Sorghum drummondii* Stapf; and
- *Sorghum verticilliflorum* (Steud.) stapf.

The taxonomy and evolution of sorghum is well known and documented. The cultivated sorghum, *S. bicolor* (L. Moench) is made up of two cross-compatible subspecies, *bicolor* and *arundinaceum*. *Bicolor* is derived from the domestication of *arundinaceum*. *Arundinaceum* has five races; two of these are proposed to be the progenitors of cultivated sorghum in different parts of Africa. Race *arundinaceum* is a forest grass in West Africa and proposed to be the progenitor of one specific race of *bicolor*. Race *verticilliflorum* is a savannah grass, which is proposed to be the main progenitor of cultivated sorghum. The ease of cross-compatibility of wild with cultivated sorghum leads to continuous gene flow in the domestication continuum, which also results in weedy intermediates. Such a genetic scenario has implications for breeding sorghum, especially in the use of wide crosses to incorporate specific traits (e.g., disease or pest resistance) into improved varieties. Molecular breeding and some new biotechnological tools would be required for such difficult crosses.

Conventional Approaches/Classical Breeding

A generalized sorghum breeding scheme is presented in Figure 3. This is a flow diagram for a systematic

	Germplasm Acquisition ↓	
	Breeding and observation nurseries – Farmer participation ↓	Initial screening Germplasm evaluation
SMIP nurseries Country crossing blocks	Crossing program Backcrossing program ↓	Line development Hybrid parent development
Breeding lines SMIP Nurseries and semifinished Products selected by advanced NARS into their nurseries	F4/F5 lines Modified Pedigree breeding Trait management ↓	Early generation testing in one location
SMIP nurseries SMIP test locations	F6/F7 Lines Population breeding Recurrent selection New Line Trials/Testcross Evaluation Line Testing; Ver. Developt. from populations ↓	Advanced generation testing in 1–2 locations. Head bagging of 2–3 plants/line for seed increase Replicated trial in 2–3 locations Selection based on visual observations and analyzed data. 1 year duration
NARS specific selections of Breeding lines from SMIP test Locations	Preliminary cultivar testing – new varieties, new hybrids – new hybrid parental lines and restorers ↓	1–2 years 2 locations
NARS selection and Promotion of advanced	Regional advanced cultivar testing ↓	1st stage regional collaborative trials of NARS and regional networks
Materials into their national variety trials	Bilateral cooperative trials – specific to requesting NARS Regional collaborative trials – across all countries and agroecologies ↓	Beginning of multilocational trials- regional in 4 locations across region NARS in 6–10 country locations Joint NARS/network evaluation 2–3 years for variety replacement 6–10 locations in cooperating countries and partners/stakeholders
Breeder seed increase Seed production training by SMIP regional and in-country	National program testing (on-station) ↓	NARS activity in national experiment stations, multilocations, advanced testing, compilation of data. 2 years
Large-scale seed production (NARS and industry)	(on-farm testing)	Major farmer involvement to identify farmer preferences and release of varieties by NARS. 2 years, multifarm locations. NARS and stakeholder activity
More breeder seed increase (NARS and network)	On-farm verification ↓	
Variety description and production of leaflets	Cultivar release, seed multiplication farmer adoption and production	NARS activity facilitated by partners, NGOs, seed producers, farmer groups

Figure 3 A generalized example of sorghum breeding scheme for achieving impact.

and logical breeding and selection approach for both short-term and long-term (Table 1). The procedures include:

- germplasm acquisition and assemblage, characterization, evaluation, and trait identifications (prebreeding);
- identification of parents followed by crossing program, including hybrid development;
- the selection and testing process;
- population improvement and recurrent selection;
- line testing, variety identification/development, verification, and release; and
- seed systems and issues for a breeder.

Germplasm Assemblage and Utilization

Traditional breeding has been mostly limited to agronomically significant and specific genetic resources. Such sources have been, for example, the zera zera (which are mostly caudatum race) from Gambella

Hills of Ethiopia, the kaffir sorghums from southern Africa giving rise to the converted combine kaffirs in the USA, and the guinea race sorghums from West Africa. The guinea race sorghums are also used extensively in the conversion programs of United States Department of Agriculture – Agricultural Research Service (USDA-ARS) and INTSORMIL. There is a greater need now, more than ever, to use more of the photo-sensitive West African guineas; the yellow endosperm sorghums (Kaura types) from Nigeria, Mali and parts of southern Sudan; the very hard grain sorghums Kenike (called rice sorghums) of Mali and parts of West Africa; the durra race (mostly from West Africa); and the Maicellos Creolos (of Central America) to benefit from their unique attributes. Using these genetic resources, *per se* or in crosses, will also result in more diversification of presently available genetic bases of improved sorghum.

Classic examples of germplasm utilization from acquired resources in sorghum include:

1. the Texas A&M – US Department of Agriculture (USDA) sorghum-conversion program (623 converted lines released globally),
2. the ICRISAT/ Southern Africa Development Community (SADC) sorghum and millet improvement program working collections at Matopos (total 12 350 accessions from across the globe, leading to 27 improved varieties released, 748 breeding lines, and hybrid parental lines made available

to national program scientists and universities in Africa), and

3. the ICRISAT/ Latin American Sorghum Improvement Program (LASIP)- Latin American Commission of Sorghum Researchers (CLAIS) regional sorghum program for Central America.

Choice of Parents, Crossing Program, and Hybrid Development

Parents, be they varieties, breeding lines, or populations, are identified and chosen from information derived from characterization and evaluation of acquired (locally collected or introduced) genetic resources, and also from previous information and experimental results. The choice of parents to be used in a crossing program depends on the objectives of the program, traits of concern, and product desired.

Normally a self-pollinating plant with perfect flowers (both male and female organs are present in the same floret), crossing (hybridization) in sorghum is achieved mostly by removal of the three anthers from the floret to be crossed, before dehiscence. Alternately, the anthers could be prevented from dehiscing and releasing pollen. With the two alternatives, only foreign pollen from other selected plants or panicles (male parent) will be allowed to pollinate the plant selected as female parent. The two alternatives are referred to as emasculation and can be done by hand (physical removal of anthers) or by double plastic bag methods. The latter method allows hot moist air build-up in the plastic bag and prevents the bursting of the already swollen and mature anthers at the time of pollination with outside pollen. Crossing (setting up of panicle to be crossed and actual pollination) using these methods requires a skilled breeder or trained breeding technician. Success from emasculation or plastic bag methods is variable, depending on the sorghum type, the environment, and skill.

Crossing can be done either by hand-pollination, following emasculation in normal male-fertile plants (to develop lines from F1), or by use of male-sterility systems. Male sterility is used to make crosses for developing commercial hybrids (cytoplasmic genetic male sterility (CMS) is used) and populations (genetic male sterility, which allows for segregation in resulting crossed plants, is used). In the development of hybrids using male sterility, several CMS systems found earlier can be used, but with differential successes. The distinct CMS systems which are available are A1, A2, A3, A4, and 9E – all with diverse trait combinations, and characteristics (advantages and disadvantages) but having a common trait of no-pollen shed. A5 and A6 cytoplasms are not distinct. Fertility restoration is a problem in A2 cytoplasm; testcrosses (experimental hybrids) developed with it are mostly partially sterile. A3 cytoplasm male-sterile plants have plump yellow anthers that are difficult to distinguish from fertile anthers, though no pollen is shed. A4 and 9E are not commonly used in sorghum though it is easier to develop seed parents (male-steriles) with A2, A3, and A4 cytoplasms, than with A1.

There are different types of sorghum hybrids that can be developed using the CMS systems, depending on the expected output and the use to which the products would be put. These include: two-way F1 ($A \times B$), three-way F1 [$(A \times B) \times C$], and four-way or double-cross F1 [$(A \times B) \times (C \times D)$] hybrids. Another form of hybrid is a top-cross hybrid, derived from pure line parent crossed unto a random-mating population for synthetic variety development. Commercial hybrids are mostly developed and produced using the single-cross F1 ($A \times B$). In a few instances, three-way cross F1 [$(A \times B) \times C$] hybrids are still produced but are less productive than single cross hybrids; they can, however, be more stable and easier to produce in the field. Restorers (male parents) can be either improved varieties, pure breeding lines, or naturally existing germplasm accessions. Among the basic sorghum germplasms, studies have shown a general trend of ~20% to be natural maintainers (B-lines), 5–8% natural restorers (R-lines), and the rest, ~70%, segregated for male-fertility restoration (useful in developing new A-/B- parental lines for hybrid development).

The Selection and Testing Process

Several selection methods have been described based on expected progress and output products from selection, the skill, capacity, knowledge, and funding of the breeder. Selection methods already described in several books and published proceedings, and used for sorghum, a self-pollinated cereal crop, include:

- pure-line breeding and selection,
- individual plant selection (mass selection),
- single-seed descent selection,
- pedigree selection,
- modified pedigree selection, and
- bulk breeding and selection.

These methods usually follow a selected and advanced process in segregating generations derived from the F1 cross or backcross. Visual observations of selectable materials are used in the nursery, which should be arranged such that the two parents used in the initial cross or backcross are planted intermittently (in 1 or 2 rows) among several (6–10) rows of the segregating generations, for comparison and

ease of selection of desired recombinants. The pedigree selection method is most laborious with regard to detailed documentation of selected recombinants or derivatives from generation to generation and is mostly required in developing new male-sterile and maintainer hybrid parents. Individual plant selection is usually used in late filial generation stages (e.g., F4–F6) to purify selected new lines for purity and uniformity of desired traits. The best method to use depends on the program funding level, capabilities, experience, and knowledge about the traits being combined or managed, of the breeder.

With the identification and selection of desired recombinants, through a systematic generation advance process starting from among the F1 crosses, testing activities follow. Testing can be in the early generations when segregation is still operating, or in late generations when the lines and selections are almost pure. The best stage to carry out testing is still a debatable point, and depends on the breeder and the breeding program objectives. It is, however, necessary to understand the theory of selection among segregating populations of self-pollinated crops like sorghums and also the roles of genotype–environmental interaction.

Line, variety, or hybrid testing recognize and characterize the reaction of the test genotypes to environmental variation, which plays a significant role in determining the usefulness of a new improved genotype derived through cross-breeding. According to the generalized sorghum breeding scheme (Figure 3), a testing program begins with a preliminary replicated trial with hundreds of test entries, in one location. The testing progresses through intermediate trials (with less number of selected entries) in two to four locations, and finally to series of advanced trials and multilocational testing (now composed of few selected and elite lines, varieties or hybrids) in four to ten or twenty locations. The adaptation areas or production zones, which the new improved genotypes are meant for, would have been identified during the series of trials, from observations and recorded data.

Following a crossing program in the breeding nursery, a systematic and progressive selection system and testing program follows, for the identification and development of the most productive and adapted new lines, varieties, hybrid parents, and hybrids. Several selection methods have been described based on expected progress and output products from selection.

Population Improvement and Recurrent Selection

Random mating populations (RMPs) or composites of sorghum are developed and improved for variety of reasons. Population improvement involves generation of broad-based gene pools (population development), improvement of the RMPs through recurrent selection, and utilization of the improved RMPs for line, variety, hybrid parent, and top-cross hybrid development. The cyclic selection and recombination process simultaneously improves several traits and is important in improving polygenic traits, resulting in better performance of the superior families derived hitherto. This breeding method is supplementary to classical or conventional breeding. The improvement of populations is appropriate where there is a long-term breeding strategy, and where the myriads of recombinants and possible line developments can be capitalized upon. It, however, requires working knowledge of population genetics, genetic statistics, and quantitative genetics for understanding the theory and nature of populations. This knowledge is also essential for the ability to choose and implement the improvement cycles and recurrent selection methods.

The development or synthesis of RMPs or composites in sorghum uses genetic male sterility that allows for segregation at each stage following intercrossing. The male-sterile genes used are mainly *Ms3*or *Ms7*.

The synthesis of new populations using *Ms3* or *Ms7* takes three or four random matings with or without selection. At each cycle of synthesis, sterile plants are identified and tagged before anthesis, so that they are harvested and bulked (in equal quantities of seed) for the next cycle of synthesis. ICRISAT, INTSORMIL universities, and national programs have described several methods for population synthesis and numerous sorghum populations have been developed employing these methods, with different traits/trait combinations for different agro-ecological environments.

At the end of the third or fourth cycle of synthesis, the newly developed population is improved by recurrent selection. Recurrent selection is cyclic in nature and four main recurrent selection and two reciprocal recurrent selection methods have been described. These are S1 testing, S2 selection and testing, recurrent half-sib-selection, reciprocal recurrent selection (RRS), reciprocal full-sib, and reciprocal half-sib recurrent selection.

Both recurrent mass selection and S1 selection and testing have been most commonly used to improve sorghum populations or composites. The S2 selection is used in specific instances for multiple traits selection or to break difficult and tightly linked traits of concern. A three-stage S2 progeny testcross procedure is relatively new. This method combines full-sib selection with S1 testing and testcrossing to a desired tester. Reciprocal recurrent selection procedures use and enhance the heterosis between two populations.

It maximizes the genetic divergence between the two populations used in the improvement program focused on parental lines and hybrid development as end products.

Responses to and progress from selection in population improvement program depend on the base genetic diversity in the original (CO) population, the recurrent selection method used, the selection intensity/pressure exerted on the population cycles, the period of recurrent selection (C1, C3, or C5), type of gene action controlling the selected traits, the population size (number of plants carried forward) at each cycle of selection, and the experience of the breeder. Responses of 10–40% are common for grain and stover yields, while keeping other traits constant. These traits, kept constant normally, are associated with increases observed due to selection and testing.

Seed Issues Related to Breeding

The new lines, varieties, hybrid parents, hybrids, and populations selected are described after a series of testing and release, purified and multiplied for seeds which are provided to users. The issues of seed increase and multiplication (breeder seed) is the main job of the breeder at the end of breeding. The integrity, purity, and trueness-to-type of the product as described by the breeder must be delivered. In sorghum, of concern to the breeder are the critical maintenance of seed color, seed size and shape, glume color, panicle shape and size, plant color and height, and maturity. The production of next-stage foundation seed is a joint responsibility of the breeder, who described the material, and the seed company (small, farmer-level, medium, or large-scale), who will produce, in larger quantities, the seed provided by the breeder. The breeder need not be involved in producing certified seed for market and larger-scale accessing. The distinction between seed and grain must be understood. A seed is a reproductive organ having a living embryo and must be able to germinate. A grain is not a reproductive organ and does not have to germinate, but must be clean and containing described qualities. They are raw materials in food and feed processing but not in malting.

Nonconventional Approaches

Biotechnology and Molecular Tools

In recent times, more nonconventional breeding approaches have been used to improve sorghum. These include molecular breeding, biotechnological approaches, and farmer participatory plant breeding (PPB). These three nonclassical breeding methodologies, which are more recent scientific and socio-economic (especially PPB) tools, complement the classical breeding methods. Each of these has their specific uses, which can overlap in some instances in their complementarity with, and enhancing research in conventional breeding.

In sorghum, biotechnology tools are now being used in drought-resistance breeding by tagging quantitative trait loci (QTLs) associated with the different types of drought resistance (seedling, pre-flowering, and postflowering stages), for *Striga* resistance, and genetic mapping for linkage and genomic maps. They are also used for stem borer and midge resistance, grain quality improvement for increased protein, better digestibility, better processing, and incorporation of vitamin A (enhancing yellow endosperm sorghums) and micronutrients (especially Fe, Zn, and Ca); fodder and crop residue quality and digestibility by incorporation of *bmr* gene for brown midrib and stay-green trait gene. Newer biotechnological techniques have recently been used in developing alternative foods and industrial applications (as in using sorghum nondigestible protein character in developing biofilms for fruits and vegetable preservation for exports). These several methodologies have been described and recorded, especially for striga resistance and control, herbicide resistance, molecular and linkage mapping, population dynamics of striga, and biodiversity studies in wide crosses.

Farmer Participatory Breeding

The role of farmers and indigenous knowledge in plant breeding are combined with PPB becoming "farmer participation in plant breeding and selection (farmer participatory breeding – FPB)." This is a practical process of bringing together farming community knowledge and research capabilities with that of scientific research organizations in an interactive way. It involves breeding activities with shared responsibilities and benefits farmers and scientists/breeders, in the characterization and description of indigenous germplasm, identification of useful parents with specific traits for a crossing program, selections, testing (on-station and on-farm), and in the use of new improved breeding materials. This approach contrasts with conventional breeding methods and tools in that the farmers involved are not treated as passive subjects, but rather as active partners. Some successes have been achieved using this FPB or PPB approach in eastern and southern African countries by Centro Internacional de Agricultura Tropical (CIAT) and ICRISAT for beans, sorghum, and millets.

Production

The world production of sorghum has ranged between 54.32 million tonnes (Mt) (in 1994) and 61.39 Mt (in 1998) and decreasing to 55.00 Mt in 2002. Table 2 shows the sorghum area and production across the globe in 1994. Relative to wheat, rice, maize, and barley, sorghum ranks fifth in importance, quantitatively, accounting for 5% of world cereal production. Africa, where sorghum is mostly used for food and beverages, was the largest producer in 1998 (20.1 Mt), followed by Asia (13.5 Mt) and North America (13.2 Mt), where it is mostly used for livestock feed. Cultivated sorghums are annuals adapted to the semiarid areas and drought prone subhumid agroecosystems, with ability of the roots to continue living after harvest to support ratoon crops (second and third rations possible from the same old roots), a common practice by farmers in some parts of eastern and southern African semiarid areas. Among the cultivated sorghums, there are three main types: (1) grain sorghum for food and feed, (2) forage sorghum for silage and crop residue (fodder) mainly for livestock feed, and (3) sweet sorghum with use in brown sugar, syrups, and alcohol production. Some of the weedy and wild sorghums together with their intermediates (mostly shatter cane) are used as grazing silage and hay.

Table 2 Sorghum area and production across the globe in 1994

Region/country	*Area (Mha)*		*Production (Mt)*	
Africa (30 countries)	21.80		17.10	
East and Central Africa (7 countries)[a]		9.15		7.11
Southern Africa (11 countries)[b]		1.60		1.27[b]

America	4.90		20.38	
United States of America		4.05		17.50
Argentina		0.70		2.60
Brazil		0.15		0.28
World	40.61		54.32	

[a] Includes Sudan.
[b] Includes Tanzania and South Africa that grow hybrid sorghums.

Agronomy and Protection Breeding

There is a range of diseases and pests that constrain sorghum production. Sorghum diseases can be caused by bacteria, viruses, nematodes, and parasitic plants (witchweeds = Striga species). Bacterial diseases in sorghum are few (leaf stripe, leaf streak, and leaf spot) and cause minor yield losses. Fungal diseases are most common causing minor to very significant yield losses. They include:

1. foliar diseases – leaf blight, leaf anthracnose, gray leaf spot, sooty stripe, zonate leaf spot, rust, downy mildew;
2. panicle and inflorescence diseases – head anthracnose, smuts (head smut, loose kernel smut, covered kernel smut, and long smut), ergot, grain mold, head blight; and
3. root and stalk diseases – *Fusarium* root and stalk rots, charcoal rot, *Acremonium* wilt, twisted top (pokkah boeng), and *Pythium* root rots.

Control of these diseases, which can be simply or complexly inherited with one or multiple genes, includes use of resistant varieties and integrated disease management with crop rotation and field hygiene. Depending on the inheritance gene action for the disease, mass selection or backcrossing are most commonly used resistance breeding methods.

The common virus diseases include maize dwarf mosaic and sugarcane mosaic viruses. Root-knot nematodes and pratylenchus species which cause stunting are the common nematode diseases. The major parasitic weed in sorghum are Striga species (of economic significance are *S. hermonthica, S. asiatica,* and *S. ferbesii*. Integrated management including host plant resistance (HPR) seems to be succeeding for control of these set of diseases. Striga HPR is not yet completely successful. After ~60 years of developing resistant varieties combined with fertilizer and herbicide use, no sustained and high-level control with stable resistance has been achieved. Presently, maker-assisted selection with farmer involvement, and biotechnological tools (like restriction fragment length polymorphism (RFLPs) and QTLs) are being used to develop sustained resistance in sorghum and effective management of striga. It has and still is a scourge in African sorghum production (Figure 4).

There are large number of insects that attack sorghum. There are the soil insects, stem and head feeders and stored sorghum grain insects. Breeding for host plant resistance as control measures for insect pests has not been very successful. Avoidance and appropriate cultural practices (like timely planting, field hygiene, and use of non-toxic and cheap insecticides) have been the management for control measures used so far in sorghum. Presently however, biotechnological tools (like Bt gene) and biological control (using parasites of the insect pests) are being developed for use in sorghum insect pest control. In all, 21 soil

Period	Breeding strategy
1977–84	Bilateral conventional breeding with NARS in Sudan and Tanzania.
Phase 1	Focus: (i) Crossing and testing program using landraces as parents in sorghum improvement; (ii) Variety and hybrid development for Striga resistance and grain yield.
1984–93	Collaborative conventional breeding through networks (EARSAM, SMIP); regional breeding followed by national and regional testing.
Phase II	Main priorities: (i) Technology generation, i.e., germ plasm assembly and exchange, crosses, segregating generations, initial testing and evaluation for variety, population and line development; (ii) technology testing and utilization, i.e., on-station and on-farm trials, farmer participation in breeding and selection, focus on earliness, yield, disease and pest tolerance/resistance and dual-purpose varieties; (iii) capacity building of NARS breeding. Secondary priorities: (i) Grain-quality screening and evaluation; (ii) beginning technology transfer and exchange with producers/farmer groups and extension, for national variety releases and seed production.
1993–2002	Rationalization of breeding objectives from conventional approaches in first 20 years, to impact-oriented breeding.
Phase III	Main priorities: (i) Technology exchange: – on-farm trials and on-farm verification; – farmer-participatory breeding; – release of farmer-acceptable varieties; – breeder and foundation seed production involving private seed companies; – training of farmer groups in seed production. (ii) Target technology generation: – breeding for increasing productivity through development of higher yielding varieties, hybrids, and hybrid parents; – incorporating end-user perspectives in breeding programs; – regional breeding and testing; – continued variety releases; – spillovers across countries. (iii) Commercialization and impact: – linking producers with processors through provision of cultivars with known and use qualities; – documenting, disseminating and modifying, processing and utilization technologies with improved cultivars for food, livestock feed, malting; – expanding linkages and partnerships with private sector (millers, maltsters) and farmers' groups, for pilot testing of end use qualities; – linking/identifying improved or released varieties with market products; – closer collaboration between breeders, economists and processors/private sector seed companies; – seed systems and improving farmers' access to improved technologies. Secondary priorities: (i) promotion of improved varieties and hybrids for food products, use in industry and livestock, through breeders' involvement in pilot product development and testing with small- and large-scale commercial farmers and farmer groups; (ii) Expanded linkages with food technologists, processing industries, economists, NGOs, and ARIs for processing and utilization and market systems.

Figure 4 Sorghum research in eastern and southern Africa: an example of evolution of breeding strategies as shown in ICRISAT.

insects, 22 stem and head (panicle feeders), 8 stored sorghum grain insects, and 5 predators of sorghum insect pests, have been identified and described.

Breeding Sorghum for Specific End Uses

There is ample natural genetic variation in sorghum for several adaptive, productivity, survival value, and end-use traits. These – including storage; mechanical and chemical processing (de-hulling, milling, malting, popping, fermenting, brewing, baking, extruding); carbohydrate, fiber, protein, oil, polyphenols contents; food and livestock feed use – can be improved and selected for, through breeding. Methodologies, including conventional and nonconventional, can be used to screen, evaluate, and enhance the quantity and quality of these normal end use and also novel traits.

Table 3 Range of grain qualities in different sorghum types based on grain colour; usable in defining limits for end uses in industry (cottage or large scale)

Grain trait	*Range of values*		
	White sorghum	*Red sorghum*	*Brown sorghum*
Testa	Absent	Absent	Present
Hardness score[a]	2.6–4.8	1.7–4.7	1.4–3.8
Flour yield (%)	72.60–90.82	69.23–88.20	64.20–86.20
Water absorption (%)	3.8–11.8	4.2–13.1	5.1–14.8
Flour color: (Agtrons)[b]			
Dry Agtron reading	68.2–82.5	59.5–76.8	50.7–72.1
Wet Agtron reading	48.8–63.6	32.2–55.4	24.4–48.8
Malting quality (SDU values)	14.68–73.34	15.90–72.62	28.28–74.17
Tannin content (% ce)	0	0–0.5	0.5–5.0
Crude protein (%)	10.9	10.9	10.9
Popping quality	Very good	Very good	Poor
Visual hardness	2.4–3.0	3.0–3.4	1.0–2.5[c]
Grain size[d]	Medium–large	Medium–large	

[a]Hardness score on a 1–5 scale where 1.0–2.5 = soft, 2.6–3.4 = intermediate, 3.5–4.5 = hard, and 4.6–5.0 = very hard.
[b]The higher the reading, the lighter is the product color.
[c]Brown sorghums do not pop well as the grains are too soft.
[d]Grain size: large = grains > 4.00 mm, medium = grains 4.00–2.60 mm, small = grains < 2.60 mm.

Table 4 Range of whole plant qualities in different improved sorghum types for silage (Animal feed) in drought prone and adverse environments

Traits	*Silage use*	
	Dairy cattle	*Beef cattle*
Plant type	Tall, long season, bulky, and tillering; purple or tan color	Semidwarf, short to medium season, bulky or tillering, tan plant color
Green biomass	High (70–120 t ha^{-1})	Medium to low (60–40 t ha^{-1})
Dry matter (DM)%	Low to medium (28–35)	Medium to high (35–55)
Metabolizable energy (ME)	9–11 MJ	11–13 MJ
Convertible protein (CP)	5.0–8.0%	5.0–7.0%
Crude fiber (CF)	25–30%	22–35%
Examples of improved cultivars with the desirable traits combination	PATO SDS 2690-2	PHOFU/MACIA Town

The evaluation of grain quality of improved sorghum cultivars for several end uses, should be a complementary activity of breeding programs. Thus, while breeding improved genotypes for adaptation and productivity, their grain qualities together with those germplasm accessions or genetic stock used in their improvement, should also be assessed for processing and utilization technologies. Simplified methodologies for grain and product quality evaluation of sorghum has been described. These include qualitative and quantitative methods, chemical analyses, product preparation, and testing. One such database was generated on 2500 genotypes (including improved and farmer varieties) for 14 grain quality traits, analyzed in a period of 2–6 years. Such databases have been used to characterize and classify sorghum genotypes for what end uses, develop grading systems and quality standard for sorghum as raw materials in industry. This complementary breeding activity has been found to enhance and increase adoption rates for sorghum varieties and hybrids and generated impact in farmers' fields and industry.

Tables 3 and 4 show the ranges for grain qualities in different sorghum types based on grain color, and for whole plant qualities in different sorghum types for silage in adverse environments, respectively. These are examples from mostly African sorghums that define limits for some end use qualities for product development and sorghum commercialization.

Introduction

Sorghum, *Sorghum bicolor* (L.) Moench, is an important food and feed crop in developing and developed countries respectively. Sorghum, the fifth most important cereal after rice, wheat, maize, and barley, is generally grown in marginal areas where other cereal crops would normally fail. It is, therefore, critical for food security in the semiarid tropics of Africa, Asia, and Latin America. Strides have been made in developing improved technologies (management practices and varieties) for farmers but average grain yields have remained low in developing countries. Harvesting is carried out manually and mechanically by smallholder and commercial farmers respectively. While a number of technologies exist to increase production of sorghum grain, the crop suffers damage and weight losses during storage to ravages of insect pests. It is difficult to quantify the losses due to handling and storage, especially in the developing countries, but most literature on the subject cite up to 20%. Therefore, the issue of inadequate storage is paramount. There is need to preserve the quality by preventing insect pests from getting into the grain. Farmers use various ways to store the grain. Both traditional and improved storage structures have their advantages and disadvantages. Improved grain storage techniques are an improvement on the inadequacies found in the traditional methods so that the stored grain does not deteriorate in quality. Therefore, the primary aim of grain storage is to prevent crop and monetary losses resulting from various agents such as rain, insect, fungi, and rodents by maintaining the quality and quantity of the grains from the beginning of storage up until it is consumed or sold. Transport of sorghum is restricted in developing countries as the crop rarely reaches the market. The crop is usually grown by smallholder farmers, largely for domestic consumption. Commercial producers use trucks, rail, and barge for grain movements to domestic and foreign markets.

Harvesting of Sorghum

The total sorghum area harvested worldwide in 2002 was 45 566 239 ha, 55% of which was harvested in Africa (Figure 1). India had the largest area harvested (22% of total) among all countries. Thus, developing countries have the greatest sorghum area harvested and harvest practices vary. Timely harvest is important to preserve grain quality and reduce mold damage, bird damage, insect pest infestation, and loss due to bad weather conditions. Traditionally, sorghum grains are harvested during the beginning of the dry season when the grain moisture content is low ($\sim$15–20%). It is critical for farmers to know when to harvest the grain to minimize losses. Grain should be harvested when it has become physiologically

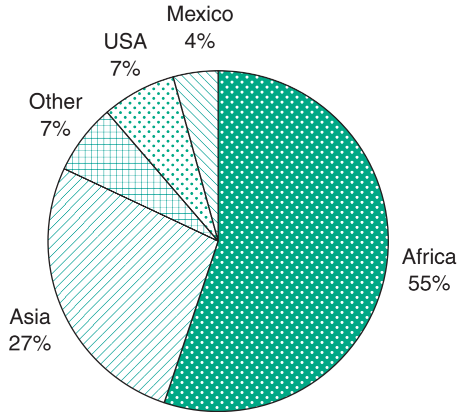

Figure 1 Sorghum area harvested (ha) in Africa, Asia, USA, Mexico, and other in 2002. (Source: FAOSTAT 2003.)

Figure 2 Manual harvesting of sorghum in Zimbabwe. The panicles are cut from the stalk when the grain moisture content is ~15–20%.

mature. Three indicators of maturity include the following:

1. a black layer forms at the tip of mature grains,
2. mature grain cannot be indented by the thumb nail, and
3. mature grain breaks cleanly when bitten with the front teeth.

Premature harvesting results in reduced grain yields while grains with lower starch, protein, and sugar content are obtained when harvesting is delayed.

In developing countries, most of the harvesting is done manually and in a few cases mechanically by combine harvesters. Smallholder and subsistence farmers harvest sorghum by cutting the heads with knives or sickles (Figure 2). Other variations in harvesting are dependent on the use of the other parts of the plant and include cutting the plants with their heads on or digging the whole plant from the roots. Sorghum stalks remaining can be used as green fodder or cut and stored as hay. The roots and stalks can be used for fuel.

In China, mechanical harvesters are designed for long- and short-stalked sorghum. Most sorghum grown in the USA and other developed countries is combine harvested. Dwarf varieties are suitable for harvest by combine. Harvesting speeds (4–5 km h^{-1}) are set to minimize combine header losses. The combine is adjusted in such a way that all grain is threshed and separated from the heads with minimum cracking and as little trash as possible is left in the grain. The grains are normally allowed to dry in the field, to allow reduction of the moisture content of 13% or less if they are going to be stored after harvesting. Varietal differences exist in suitability for harvesting with some types maintaining high moisture levels until the plants are killed by frost. Other types have a genetically conditioned head-drying character resulting in rapid drying of the grain and head after maturity. Combine harvesting can also be conducted when levels of grain moisture contents are at 20–25%, when this is followed by ensiling or artificial drying to a safe storage moisture. Where lodging from storm damage, insects, or diseases presents harvesting problems, special types of combine attachments are available to aid in harvesting the lodged fields. If lodging is excessive, the crop can be cut with a header and the heads swathed to dry before being picked up and threshed by a combine equipped with pickup attachment. Livestock are used to harvest sorghum directly as a last resort if lodging is severe and yields are low. Sorghum heads can be harvested and stored as head silage in some very humid areas where grains remain highly moist and losses to birds and weather can be substantial. The silage stores well at 25–40% moisture if it is finely cut. The grain in the head silage requires no further processing, as it is highly palatable and digestible. The stubble remaining after sorghum grain has been harvested is used as low-quality forage for fall grazing.

Drying, Threshing, and Cleaning of Sorghum Grain

Sorghum panicles should be thoroughly dried before threshing. Excess moisture is undesirable as it may lead to infestation by insects and fungi, and deterioration of quality. Partially dried heads are also difficult to thresh and too dry heads usually result in huge losses in the field while harvesting. Optimal moisture content is 10–12% for grain and 9–10% for seed. Panicles are either left in the field or transported to storage yards where the grain is left to dry. Grains are

Figure 3 Sorghum panicles are threshed to release the grains by beating the heads with sticks. Time required for threshing depends on variety and degree of dryness of the grain.

Figure 4 Grain is cleaned by winnowing so that the light chaff is carried by wind.

dried further, if necessary, after threshing, using natural and mechanical drying practices. Dryers are used commercially. Drying temperatures are limited to ~43°C and 60°C for seed and feed grain, respectively. Airflow rates of 11–28 $m^3\,min^{-1}\,t^{-1}$ are common for feed grain. Sorghum can be dried successfully at up to 94°C and airflows of 110–220 $m^3\,min^{-1}\,t^{-1}$ using batch or continuous flow dryers.

Smallholder and subsistence farmers thresh heads either manually, by beating with sticks (Figure 3) , or by using livestock to walk on the layers (~25–30 cm thick) of sorghum heads. The latter method is popular in China where animals pull a stone-roller over sorghum heads. A tractor or any other vehicle can also be driven over the heap of harvested and dried panicles. In all cases, the heads should be turned and inspected so that the action is repeated until all grains are released. Hand-harvested heads can be threshed by a stationary combine. Mechanical threshers are available that both commercial and smallholder farmers can afford. During threshing, care should be exercised to avoid physical damage to the grain. Damaged grains will deteriorate quickly in storage.

After threshing, the grain is cleaned to remove chaff (glumes, broken grain, very light seeds, and any grasses). Among smallholder farmers, women use woven trays to winnow the chaff from the grain. Alternatively, the chaff is removed by dropping the grain in a bucket against the wind (Figure 4). Chaff is also removed from the grain by sifting through a screen or sieve. The grains fall through and the chaff remains. Vibrating screens comprising of a feed hopper, sieves, dust remover, cleaner, and drive equipment are used at a commercial level. Pneumatic cleaning equipment is also available. The principle of pneumatic cleaning is to separate impurities from the grain based upon differences in specific gravities.

Treatment before Storage

There are several chemicals that are used commercially to treat the grain before storing it. Some organophosphates include pirimiphos-methyl (Actellic), malathion, fenitrothion, and iodophenphos. Traditionally, sorghum grain is treated with wood ash, sand, and mineral powders to prevent insect damage in developing countries. Botanical insecticides such as neem (*Azadirachta indica*) and pyrethrum (*Chrysantheum cinnerariafolium*) are also applied before grain is stored for a short-term period.

Storage of Grain

The objective of storage is to preserve as much as possible the value of the grain for its intended future use. Either the food value of the grain is preserved or a high proportion of viable seeds are retained for planting next season. Some attributes such as a hard endosperm found in some traditional varieties, contribute to reduced pest attack during storage. On the other hand, improved varieties mature early and generally have a soft endosperm, thus, making them more prone to pest attack. Factors leading to loss of viability and nutrients include depredations by pests (insects, birds, and rodents) and also mold damage. Germination of grain causes losses on a smaller scale. Physical factors contributing to losses include moisture content of the grain and the temperature of storage. Losses increase as moisture content and temperature of the grain increase. Minor changes in temperature during grain storage lead to moisture migration and accumulation in certain areas that are cooler than the rest. This often allows microbiological activity to occur in comparatively dry grain, which in turn leads to heat production. Moist areas

in unventilated areas can get so hot that charring can occur resulting in grain destruction. Moisture migration can be prevented by forcing low volumes of air ($0.11-0.27\,m^3\,min^{-1}\,Mg^{-1}$) through grain held in silos or tanks. Aeration fans can also be installed to draw cold air down the grain while moving the warm moist air to the outside. Regular inspection of the grain is essential to detect moisture changes, insects, and spoilage during storage.

Methods for storing grain are generally influenced by the value of the crop, quantity stored, and environmental conditions. Grain augers are used commercially to place grain in metal bins. Storage bins are best filled early in the day when air is cool and humidity is often at its lowest. Grain should be packed as tightly as possible to minimize space for insects to move around and to breed. In some developing countries, sand is mixed with grain to further reduce the free space. Very often smallholder farmers store seed without treatment. This often results in the seed getting badly damaged by insects before planting. Table 1 lists the common methods of grain storage based on tradition, cost, and convenience.

Containers for Storage

Silos, bins, baskets, and other storage containers are made from a number of different materials (Table 1). There is not much need for bulk storage for smallholder and subsistence farmers in developing countries. Clay pots are used on the smallest scale. Larger containers are constructed from wood, brick, or stone, or from bamboo made into a basket that is then sealed with mud or dung. Containers can sometimes be left uncovered if kept indoors or covered with either a lid or a thatched roof if kept outdoors. Grain for immediate consumption is usually stored in the house in metal or plastic bins. However, grain can also be packed in suitable material (jute bags, cloth bags, cardboard cartons) for short and long-term storage. The grain is taken out of the bags and dried in the sun by spreading on the floor or on a sheet at regular intervals during the dry season. Exposing grain to the sun and heat at intervals keeps away storage pests. Occasionally, sorghum heads are stored on the ground; usually unthreshed. Panicles from the heaped pile are removed and threshed when grain is needed. It is generally not recommended to store unthreshed grain on the heads.

Table 1 Common methods used for sorghum grain storage

Method of storage	*Quantities*	*Construction materials*	*Cost*	*Dis-advantages*
Bulk silos	Large	Steel, aluminum, concrete	High	Costly to operate
Drums and bins	Medium	Metal	Medium	Poor ventilation
Pots	Small	Clay	Low	Poor ventilation
Pits	Large	Brick, cement, mud walls	Low to medium	Prone to mold growth
Baskets	Medium to large	Stalks, mud, cow dung	Low	Prone to pest damage
Bags	Small to medium	Cloth, sack, jute	Low to medium	Prone to pest damage

Storage Structures

The idea of storage structures is to prevent insect pests and rodents from attacking the grain. Storage structures are many and are varied in the way they are constructed. Bulk silos of heights of 30–50 m are used commercially for centralized storage. In many countries, small granaries are made by weaving plant materials, such as bamboo, stalks, bark, and small branches, and then sealing any gaps with mud or dung. These structures can either be built directly on the ground or raised off the ground on platforms or stilts (Figure 5). The store should be dry, with low humidity. The bags must be stacked on wooden pallets so that bags do not touch the ground. The structures could either be raised on a platform or built on the ground. Traditional storage structures vary according to regions and countries. For example, in southern Africa, a thatched roof is usually placed on top of a granary (Figure 6). In Nigeria, sorghum is stored as unthreshed heads in a solid walled container called a "rumbu." Heads are laid out individually for long-term storage (3–6 years) or in bundle layers for short-term storage (<3 years). When filled, the rumbu is sealed with clay. In Sudan, pits holding 2–5 t of

Figure 5 Sorghum panicles are dried while being kept off the ground on raised platforms.

grain are used as underground stores. In India, underground pits may be located underneath the houses or outside. The pit is lined with paddy straw or sorghum straw and then covered with straw and soil when it is full of grain. The top is plastered over with mud for longer storage.

Storage Pests

Insects are the most serious pests of stored products and can reduce the amount of grain harvested substantially. A good understanding of the important types of insects and their behavior will significantly help in their control. The important insect pests of stored products are either beetles or moths. These insects can be divided into two groups namely, primary and secondary insects. Primary insects are those that are able to attack undamaged grain cereals such as the Angoumois grain moth (*Sitotroga cerealella*), large grain borer (*Prostephanus truncatus*), and weevils (*Sitophilus* spp.). Secondary pests such as flour moths and flour beetles (*Tribolium* spp.) can only attack stored commodities, which have previously been damaged by either primary pests or through processing (shelling or milling).

Figure 6 Example of granary used for storing sorghum in Zambia. Smallholder farmers store grain threshed or unthreshed.

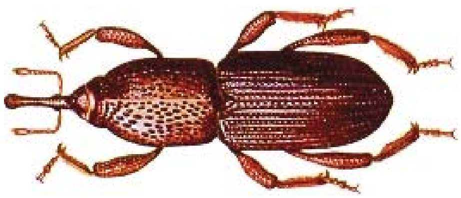

Figure 7 The rice weevil (*S. oryzae*) infects sorghum grain at moisture contents ranging from 10% to 16%. Soft endosperm types are less resistant than sorghums with hard endosperms.

For sorghum, the most important pests are the rice weevil (*Sitophilus oryzae*) (Figure 7) and grain moth (*S. cerealella*) (Figure 8). Infestation by these pests often starts when the crop is drying in the field, but there can also be carry-over from storage. Recently, the larger grain borer (*Prostephanus truncatus*) has been reported spreading into sorghum-growing areas in the southern African region (Figure 9).

Figure 8 The Angoumois grain moth (*S. cerealella*) attacks sorghum in the field. It multiplies rapidly if sorghum is stored unthreshed.

Figure 9 The larger grain borer (*P. truncatus*) has also been reported as a storage pest of sorghum.

Weevils (Rice Weevil – *S. oryzae*)

Both adults and larvae feed on grain, damaging it beyond use. The adult female bores a hole in the kernel and deposits a single egg. A female can lay 300–500 eggs. The egg hatches into a legless white larva (grub) after 3 days. The larva becomes mature in 3–6 days and adults can live for 5–6 months. In most cases, eggs are carried on grain harvested from the field.

Moths (Angoumois Grain Moth – *S. cerealella*)

Angoumois grain moth infestation can begin in the field. Attack in storage is confined to the upper layer of the grain and surfaces of bags containing the grain. The larvae bore into grain, where they feed, pupate, and finally emerge as adults, leaving round holes in the grain. The infested grain is completely hollowed out and filled with larval excreta and webbing. The larval period is 2–3 weeks and the pupal period 1 week. The adult moth does not eat the grain.

Control of Insect Damage

Insect damage can be greatly reduced by preventive action. The following practices can limit the initial infestation of the stored grain.

1. To avoid infestation of the new crop, the old grain must be removed preferably before the new crop is mature, but certainly before the mature crop is brought to the homestead. Old grain from the previous season is often a major source of insects.
2. The new crop must be rapidly dried to attain safe moisture content levels and threshed as soon as it is dry. The grain is then treated and put into store before any significant damage has occurred.
3. Before the new crop is brought in, the storage structure and its surrounding should be well cleaned and maintained.
4. The product going into the store should be: (a) well dried, (b) well cleaned, and (c) undamaged (sound). Any damaged grain should be removed and consumed first.
5. The storage structure should have no entry points at all times to prevent re-infestation with insects.
6. Adequate system of inspecting the grain throughout the storage period should be put in place.

If any pests or damage is detected, immediate action should be taken through the following exercises: (1) repairing any damage to the storage structure if necessary, (2) cleaning and drying the grain either by sunning or kilning, (3) treating the grain again with a suitable insecticide such as pirimiphos-methyl (Actellic) or pyrethrum dust, or with wood ash if necessary.

Insecticides

Insecticides provide a good protection against insects in storage due to their residual effects. There are several dust insecticides on the market that are recommended for use to control insects in stored grain. In southern Africa, commonly used dust insecticides include Actellic super dust, Chirindamatura Actellic super dust, and Shumba super at application rates of 25 g per 50 kg of threshed sorghum. These are most effective when they are admixed with threshed grain. Aluminum phosphide or phosphine, also known under trade names such as phostoxin, phosphume, phostek, is used for indoor fumigation of grain as a means of controlling storage insects. It is strongly recommended by the Food and Agriculture Organization of the United Nations as it leaves no toxic residues. According to the US Environmental Protection Agency (EPA), tolerances are established at 0.1 ppm for residues of the insecticide phosphine on sorghum grain resulting from postharvest fumigation. In Botswana, phostoxin is the most commonly used fumigant.

Another common practice among farmers is to store the grain with neem leaves. Neem (*A. indica*) contains pesticidal ingredients for protection of the plant from a multitude of pests. The ingredients can affect more than 200 insect species as well as some mites, nematodes, fungi, bacteria, and even a few viruses. Neem substances have protected stored sorghum and other foods against pests for up to 10 months in some very sophisticated controlled experiments and field trials. The main compounds belong to a general class of natural products called triterpenes or limonoids. Azadirachtin, salannin, meliantriol, and nimbin are the best known among neem limonoids. Azadirachtin repels and disrupts the growth and reproduction of insects; salannin, and meliantriol both inhibit insect feeding; and nimbin manifests antiviral activity. Neem leaves contain other ingredients shown to disrupt the fungi that produce aflatoxin on moldy cereals, legumes, and other foods. Although the fungi remain alive, it switches off their ability to produce aflatoxin, the most powerful carcinogen known.

Selection of a Storage Structure

To store grain properly and successfully the storage structure must provide an environment, which prevents grain losses and maintains the grain in good condition until it is consumed or sold. Therefore, the storage structure must be able to:

1. keep the grain dry – the grain must be protected against rain and ground moisture. An increase in

moisture content encourages germination, mold, and insect development;
2. protect the grain against pests – a well-constructed storage structure should provide a barrier against rodents and insect re-infestation;
3. keep the grain temperature low – a low and stable temperature will reduce insect and mold development. Uneven temperatures cause moisture migration in storage; and
4. facilitate easy cleaning and inspection – grain stored in a clean and tidy storage structure is less prone to deterioration.

Smallholder farmers can use better storage structures such as the improved mud-plastered grain bin for on-farm grain storage.

Fungal Contamination of Stored Sorghum

Mycotoxins are poisonous chemicals produced by the growth of fungi on grain, oilseeds, and other materials. Mycotoxigenic fungi such as *Aspergillus*, *Alternaria*, *Fusarium*, *Curvularia*, and *Phoma*, and mycotoxins such as alternariol, alternariol monomethylether, patulin, trichothecenes, zearalenone, altenuene, altertoxin I, aflatoxin B_1, B_2, G_1, and G_2, and T-2 toxin have been reported in sorghum under certain environmental conditions. Storage fungi of the genera *Aspergillus* and *Penicillum* can be produced on grain stored with moisture content greater than 13%. Aflatoxin produced by *Aspergillus flavus* in sorghum is the most carcinogenic of the known mold metabolites. For example, pigs can tolerate only 0.23 ppm in their feed. Aflatoxin has been shown to be hepatotoxic, carcinogenic, mutagenic, and teratogenic. Proper drying and storage would greatly prevent the contamination of food grains with these mycotoxin-producing fungi. Failure to dry grain or prevent accumulation of moisture through condensation favors the growth of molds. Under conditions of 30–40°C, aflatoxin can be produced within 2–6 weeks, and signs of mycotoxicosis of pigs may be noticed within a week of it being introduced into the diet. The total quantity of the food to be consumed and the animal (including humans) for which it is intended will both influence what is considered a "safe" tolerance limit. Young infants are more sensitive than healthy adults. Many grain-importing countries enforce regulations on mycotoxin levels set by the Codex Alimentarius Commission. To avoid or minimize grain contamination by mycotoxins, proper agronomic, storage, handling, and inspection practices should be implemented.

Transport

Transport of grain is an important component and is varied. An efficient transport mechanism is needed to get the produce from the field to storage warehouses and ultimately to markets. Compared to other cereal crops, sorghum is not widely traded internationally; and within those developing countries where they are grown for human food, there is usually a balance between local production and local demand. Smallholder farmers use oxen-drawn carts or trailers to transport farm requisites and farm produce. Donkeys are also widely used as well. Sorghum heads are harvested in the field and placed on a cart to the threshing area. In many cases, women transport the harvest in baskets on their heads. The produce can also be taken to markets. Intermediate and other larger farmers use either tractors or trucks to get their produce to storage areas and markets.

In developed countries, considerable movement occurs not only within surplus grain areas but into export channels and into feed-deficit areas. Sorghum for animal feed is transported mostly by rail or truck. The former is considered the best for distant shipments whereas the motor truck is used for short shipments. The shipper's choice on both long and short hauls is based upon relative transport rates, services performed, and other costs and convenience factors. The nature of operation is reflected by the ratio of truck to rail movement. Country elevators generally have shorter distance and smaller quantity per haul. Although total shipments are small, since most of their receipts are processed, processing plants are next in distance and quantity. Terminal elevator operations generally have the longest hauls and the largest quantity per haul. Both distance and quantity for each type of handler are generally less for receipts than for shipments. Domestic shipments are also done to a lesser extent by barge. Barge shipment is primarily used for sorghum export. The USA is the largest exporter of sorghum. Argentina and Australia also produce sorghum meant for the domestic and export market. Most sorghum is exported to feed grain-deficit areas and Japan, Mexico, the former USSR, and Venezuela are the main importers. Global standards for sorghum grain trading are specified under the Codex Alimentarius Commission under Codex Standard 172-1989.

Future Prospects

Sorghum will remain an important global food and feed crop. The largest group of producers, the smallholder and subsistence farmers, can play a greater role in world sorghum production and marketing

provided they have reasonable access to production inputs, improved harvest techniques, better storage facilities, and transport mechanisms for their produce. Sorghum is poised to compete equally with rice, wheat, and maize given its yield potential and the area currently under cultivation. However, inputs similar to those provided for rice, wheat, and maize on genetics, production, and postharvest research are still to be realized.

Utilization

R D Waniska, L W Rooney, and C M McDonough, Texas A&M University, College Station, TX, USA

Introduction

Sorghum is utilized as food, feed, and industrial products around the world. About 30–40% of the 62 million metric tons (Mt) produced annually is used in a wide variety of traditional foods mainly in Africa, Asia, and Central America. Industrial production of beer, nonalcoholic beverages (*see* **Fermentation**: Foods and Nonalcoholic Beverages), and porridges (*see* **Cultural Differences in Processing and Consumption**. **Maize**: Foods from Maize) occurs in Africa, especially Nigeria, South Africa, and Botswana. Small quantities of sorghum are used for foods in the western hemisphere and in Japan. Production, plant characteristics, and related information on sorghum were presented in **Sorghum**: Breeding and Agronomy, and Harvest, Storage, and Transport.

The major use for sorghum is as livestock feeds for all species of animals. Sorghum is processed, to improve its feed efficiency, into a wide variety of feeds ranging from floating fish food to steam flakes for ruminants in large feedlots. Sweet sorghums are preferred for syrup and for forage. The forage (fodder) may be more valuable than the grain. The stalks are used for dry fodder for ruminants and some sorghums are grazed, since the stalk remains green after grain maturation. Most of the comments in this article are on utilization of sorghum grain, but forage utilization is also important in drier areas of the world.

Grading and Classification

Sorghum is marketed according to US grain standards in four classes: sorghum, white sorghum, tannin sorghum, and mixed sorghum. The sorghum class cannot contain more than 3% sorghum with a pigmented testa (undercoat). Tannin sorghums have a pigmented testa beneath the pericarp. The pigmented testa is seen as a dark layer between the light endosperm and the pericarp when the caryopsis is scraped to remove the pericarp. Bleaching using the chlorox bleach test causes the constituents in the pericarp and testa to oxidize and gives a pronounced black color to the bleached kernels while nontannin sorghums have a white appearance. The white class contains sorghum with a white pericarp without a pigmented testa and cannot contain more than 2% of sorghum with pigmented testa or colored pericarp. Mixed sorghum contains a blend of kernels with and without pigmented testa. The US also markets "Food-Grade" white sorghum, a white kernel with tan plant and glume characteristics. The amounts of anthocyanin pigments that darken these grains are less than those from grain with purple or red glumes.

Appearance and Genetics of Sorghum

Many factors affect grain appearance: pericarp color and thickness, presence of a pigmented testa, endosperm color, secondary plant, and glume colors and damage by insects and molds affect the appearance and quality of sorghum (*see* **Grain, Morphology of Internal Structure**. **Grain and Plants, Morphology**). Pericarp color is genetically controlled by the *R* and *Y* genes. The combination of these genes produces white or colorless (*R_yy* or *rryy*), lemon yellow (*rrY_*), or red (*R_Y_*) color. The intensifier (*I_*) gene increases the brightness of the pericarp color in red pericarp sorghums. Sorghums with homozygous recessive (*zz*) genes have a thick mesocarp containing small starch granules, which causes a chalky appearance that masks the colors of the testa and endosperm. A pigmented seedcoat (testa) is present when both B_1_ and B_2_ genes are dominant. Caryopses with a pigmented testa (B_1_B_2_) and a recessive spreader gene (*ss*; type II) or dominant spreader gene (*S_*; type III) contain condensed tannins and are brown (tannin) sorghums. The *tptp* genes control testa color, which is brown or purple. Type III sorghums have more tannins than type II sorghums. Type I sorghums do not contain tannins (proanthocyanidins).

Yellow endosperm cultivars contain 8–30 ppm carotenoid pigments. Endosperm color affects appearance, especially in caryopses with a thin pericarp and without a pigmented testa where the grain appears to be yellow. A thick mesocarp and colorless pericarp cause a white or chalky appearance. Heteroyellow endosperm sorghum results when sorghums with yellow and nonyellow endosperm colors are hybridized. Bronze sorghums contain a thin, red pericarp with yellow endosperm color, while cream sorghums contain a thin, white pericarp with yellow endosperm.

Waxy endosperm cultivars contain three genes (*wx*) in the recessive form. Heterowaxy genotypes contain one or two of these genes in the dominant form whereas normal or nonwaxy endosperm sorghums contain all three genes in the dominant form. Waxy cultivars contain nearly 100% amylopectin and the endosperm looks like candle wax.

The high-lysine (*hl*) sorghum from Ethiopia has a soft, floury endosperm texture, a shriveled kernel structure, and is susceptible to deterioration in humid environments during and postcaryopsis development. The improved protein digestibility sorghum and the chemically induced, high-lysine sorghum have intermediate-soft to soft endosperm textures; they have reduced grain yield and increased deterioration due to molds and weathering.

Grain Structure and Physical Properties

The sorghum kernel is considered a naked caryopsis, although some African types retain their glumes after threshing (*see* **Grain and Plants, Morphology**). The kernel weight varies from 3 to 80 mg. The size and shape of the grain varies widely among sorghum races. Commercial sorghum grain has a flattened spherical shape, 4 mm long, 2 mm wide, and 2.5 mm thick, with a kernel weight of 25–35 mg. The volumetric weight and grain density range from 708–760 kg m^{-3} and from 1.26–1.38 g cm^{-3}, respectively.

The sorghum caryopsis is composed of three anatomical parts: pericarp, endosperm, and germ (Figure 1a). The relative proportion of these

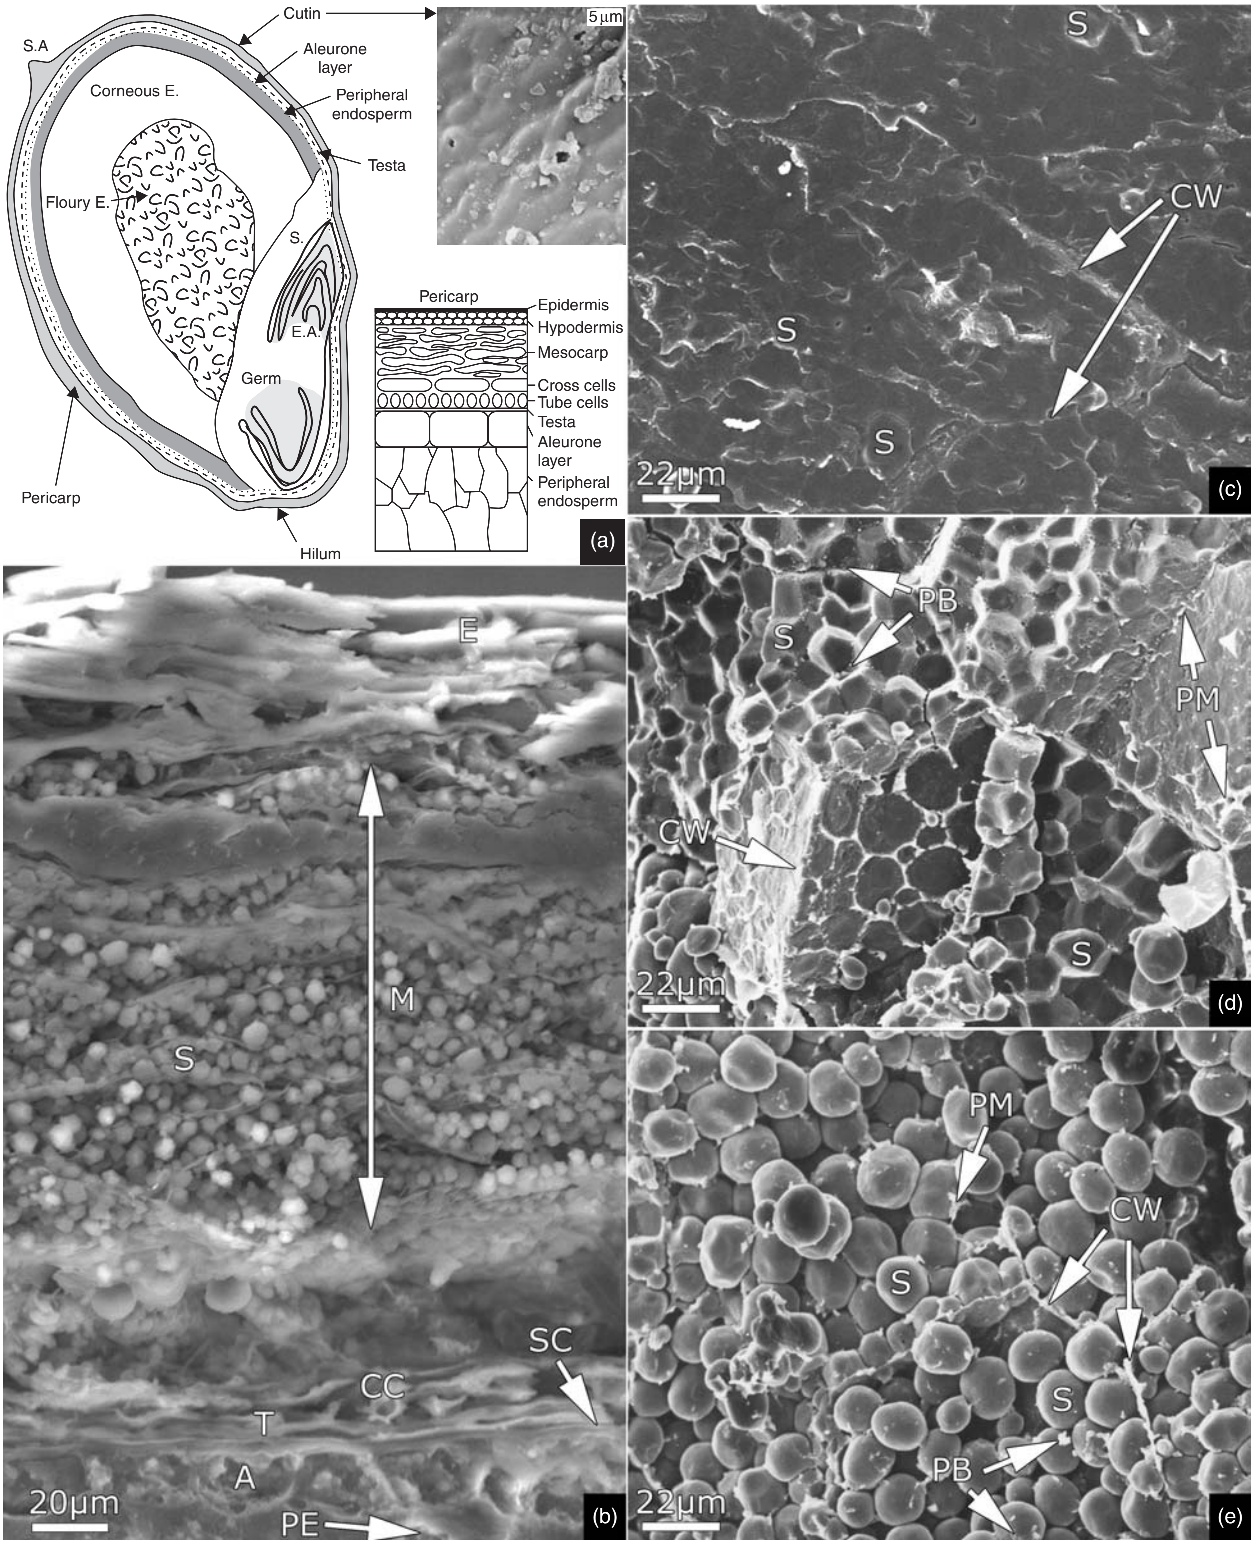

Figure 1 Scanning electron microscopy photos of sorghum microstructure. Note: (a) = cross-section of the sorghum caryopsis; (b) = a thick pericarp; (c) = peripheral endosperm; (d) = corneous endosperm; (e) = floury endosperm. Labels: A = aleurone layer; C = corneous endosperm; CC = cross cells; CW = cell wall; E = epicarp; F = floury endosperm; G = germ; M = mesocarp; PE = peripheral endosperm; P = pericarp; PB = protein body; PM = protein matrix; S = starch granule; SC = seed coat; T = tube cells. (Reproduced with permission from Earp *et al*. (2004) *Journal of Cereal Science* 39(1): 21–27.)

structures varies but in most cases is 6%, 84%, and 10%, respectively. The pericarp (Figure 1b) is the fruit coat and is fused to the sorghum seed. It originates from the ovary wall and is subdivided into three distinctive parts: epicarp, mesocarp, and endocarp. The epicarp is the outermost layer and is covered with a waxy film. The mesocarp varies in thickness and thick mesocarps contain starch granules. The endocarp is composed of cross and tube cells and plays a major role in transporting moisture and nutrients during germination and development.

The true seed consists of the seedcoat (testa), endosperm, and germ (*see* **Grain, Morphology of Internal Structure**). The endosperm tissue is triploid, resulting from the fusion of a male gamete with two female polar nuclei. The testa (seedcoat) is derived from the ovule integuments; in brown sorghums, it is thick and contains condensed tannins. The testa is pigmented when the genes are $B_1\_B_2\_$, The endosperm is composed of the aleurone layer, peripheral, corneous, and floury areas. The aleurone consists of a single layer of rectangular cells adjacent to the tube cells or testa. Aleurone cells contain a thick cell wall, large amounts of proteins (protein bodies) and enzymes, ash (phytic acid bodies), and oil bodies (spherosomes). The peripheral endosperm (Figure 1c) adjacent to the aleurone layer is a hard layer composed of dense cells containing large quantities of protein and small starch granules. These layers affect the processing and nutrient digestibilities of sorghum. Processing of sorghum by steam flaking, micronizing, popping, and reconstitution is designed to disrupt the endosperm structure to improve the digestibility.

The corneous and floury endosperm cells are composed of starch granules, protein matrix, protein bodies, and a thin cell wall rich in β-glucans and hemicellulose. In the corneous endosperm, the protein matrix surrounds the starch granules and protein bodies are embedded in the matrix (Figure 1d). The starch granules are shaped polygonally and often contain dents from protein bodies. The appearance is translucent and the texture vitreous. The opaque-floury endosperm is located around the geometric center of the kernel. It has a discontinuous protein phase, air voids, and loosely packaged, round-angular starch granules, and is opaque to transmitted light (Figure 1e).

The germ is diploid owing to the sexual union of one male and one female gamete. It is divided into two major parts: the embryonic axis and scutellum. The embryonic axis forms the new plant and is subdivided into a radicle and plumule. The radicle forms primary roots, whereas the plumule forms leaves and stems. The scutellum is the single cotyledon of the sorghum seed. It surrounds the embryonic axis, contains large amounts of oil (spherosomes), protein, enzymes, and minerals, and separates the endosperm and germ.

Composition

Sorghum grain composition (Table 1) is significantly affected by genetic and environmental factors. Starch (75–79%) is the major component, followed by protein (9.0–14.1%), and oil (1.5–5.0%). The protein content ($N \times 6.25$) of sorghum is more variable and usually 1–2% higher than maize. Approximately 80%, 16%, and 3% of the protein is in the endosperm, germ, and pericarp, respectively. Sorghum generally contains 1% less oil and significantly more waxes than maize.

Starch

Sorghum starch is composed of 70–80% amylopectin and 20–30% amylose. Waxy sorghums contain starch with 100% amylopectin; their properties and uses are similar to those of waxy maize. The gelatinization temperature of sorghum starch is slightly higher than that of maize starch; however, it can be used interchangeably with maize starch. Sorghum starch from the hard endosperm is difficult to separate from the protein matrix. The wet milling of food-type sorghums produces excellent prime starch. Sorghum endosperm requires a little longer to cook compared to maize endosperm particles. Sorghum endosperm can be easily extruded into a wide variety of snacks and other ready-to-eat products.

Table 1 Composition[a] (%, unless otherwise stated) of sorghum grain

Component	*Value*	*Range*
Protein ($N \times 6.25$)	11.6	8.1–16.8
Albumins	5.7	1.6–9.2
Globulins	7.1	1.9–10.3
Prolamins	52.7	39.3–72.9
Glutelins	34.4	23.5–45.0
Lipid	3.4	1.4–6.2
Ash	2.2	1.2–7.1
Nitrogen-free extract	79.5	65.3–81.0
Fiber		
Crude	2.7	0.4–7.3
Dietary, insoluble	7.2	6.5–7.9
Dietary, soluble	1.1	1.0–1.2
Acid detergent	3.3	2.9–3.6
Sugars	2.1	1.3–2.6

[a] All values are expressed on a dry-matter basis. Nitrogen-free extract was calculated by difference.
Adapted from Rooney LW and Waniska RD (2001) sorghum food and industrial utilization. In: Smith WC and Frederiksen RA (eds.) Sorghum: Origin, History, Technology and Production, pp. 689–725. Wiley.

Soluble Sugars

Mature kernels contain 2.2–3.8% soluble sugars, 0.9–2.5% free reducing sugars, and 1.3–1.4% nonreducing sugars. Glucose and fructose comprise 0.6–1.8% and 0.3–0.7%, respectively. High-lysine and sugary cultivars contain additional simple sugars and amino acids, which accounts for the flavor they develop during roasting.

Fiber

Most of the fiber is present in the pericarp and cell walls. Sorghum contains 6.5–7.9% insoluble fiber, hemicellulose and cellulose, and 1.1–1.2% soluble fiber, β-glucans and pentosans. Sorghum contains ~1.3% pentosans, located mainly in the pericarp. Approximately 70% of the pentosans are alkali-soluble, and 30% are water-soluble. Fibers in cell walls of the aleurone and endosperm are associated with ferulic and caffeic acids. Fibers in the pericarp provide structural and protective functions; therefore, fiber content of sorghum products depends on the extent of pericarp removal during milling.

Insoluble dietary fiber increases during food processing due to increased levels of bound protein, mainly kafirins, and enzyme-resistant starch. In tannin sorghum, cooking also forms polyphenol–protein complexes, which increases bulking ability. Sorghum brans do not lower blood cholesterol levels but are excellent bulking agents in rats. Sorghum bran fed to humans increases stool weight, decreases intestinal transit time, and increases the frequency of bowel movement.

Proteins

Protein content and composition vary due to agronomic conditions (water availability, soil fertility, temperatures, and environmental conditions during grain development) and genotype. Nitrogen fertilization significantly increases kafirin accumulation and protein content. Kafirins (the sorghum prolamin proteins) and glutelins comprise the major protein fractions in sorghum. These fractions are primarily located within the protein bodies and protein matrix of the endosperm, respectively. The alcohol-soluble prolamin fraction comprises 50% of the protein. These proteins are hydrophobic, rich in glutamine, leucine, alanine, and proline, contain little lysine and are primarily located within protein bodies. Kafirins contain cross-linked proteins that slow digestibility of the protein. Sorghums identified with easier to digest proteins have protein bodies with a modified structure and contain less kafirin and less cross-linked protein after cooking. Glutelins are high-molecular-weight proteins, mainly located in the protein matrix. The lysine-rich protein fractions, albumins and globulins, predominate in the germ.

Lysine and threonine are the first and second most limiting amino acids in sorghum proteins. Sorghum lysine meets ~40% of the recommended level for infants. High-lysine cultivars contain ~50% more lysine. They are soft, dented, contain lower levels of kafrins and higher levels of glutelins, and salt-soluble proteins.

Lipids

The germ contains 80% of the ~3.5% lipid in the sorghum caryopsis. The fatty acid composition consists mainly of linoleic (49%), oleic (31%), and palmitic (14.3%) acids. Refined sorghum oil is very similar to maize oil in quality and fatty acid content. The reduced oil content of sorghum compared to maize is an advantage for some applications in food products, i.e., extruded whole grains and some brewing operations where whole grains are used with industrial enzymes to produce lager beer without barley.

Waxes form protective films on the surface of the leaves, stalks, and pericarp of the grain of sorghum (*see* **Oil from Rice and Maize**). The surface of the pericarp contains up to 0.5% wax, which has properties and composition similar to carnauba wax. The low amount of wax limits commercialization but the economics could improve as a by-product recovered from distillers grains during alcohol production.

Vitamins and Minerals

The germ and aleurone are rich in fat-soluble and B-vitamins. Sorghum contains 0.3–0.8 μg per g α-tocopherols and 9–11.5 μg per g τ-tocopherols. Precursors of vitamin A (carotenes) are found in yellow and heteroyellow endosperm sorghums. Yellow endosperm sorghum caryopses contain 1.5–30 ppm of carotenoids: 36.3% zeaxanthin, 28.6% lutein, 24.7% xanthophyll, and 10.4% β-carotene. Weathering causes sorghum to lose 50% of its carotenoids.

Sorghum is an important source of minerals that are located in the pericarp, aleurone layer, and germ. Phosphorus is the mineral found in greatest amounts; its availability is negatively related to the amount bound by phytates. Phytase activity during malting and fermentation significantly increases availability of phosphorus and other minerals as well.

Enzymes

The sorghum aleurone layer is not a major source of endosperm-degrading enzymes. The scutellum of sorghum is where α-amylase is formed and diffuses into the endosperm. Sorghum does not respond to gibberellins to enhance production of amylases during

malting. The α-amylase activity in sorghum starts 24–36 h after germination. A rapid increase in dextrinase activity is observed 24 h after germination. Limit dextrinases and proteases are found mainly in the endosperm, whereas, carboxypeptidases are located primarily in the germ. Sorghum malt has high levels of α-amylase activities but it has reduced β-amylase activities.

Tannins and Phenols

Condensed tannins (proanthocyanidins) are not present in all sorghums; however, all sorghums contain phenolic acids, and most contain flavonoids. Kernels that contain condensed tannins have a thick, highly pigmented testa. These sorghums were referred to as brown sorghums but are now classified as tannin sorghums. Tannins protect the kernel against preharvest germination and attack by insects, birds, and molds. Birds consume brown sorghums when other food is unavailable. Animals fed tannin sorghum rations eat more feed and produce about the same amount of gain, so feed efficiency is reduced. There are no toxicity problems but feed efficiency is reduced by the condensed tannins. This situation is grossly misstated in the literature, because there have been numerous feeding trials reporting decreased feed efficiency with only a few instances of other problems.

The condensed tannins have a high affinity for prolamin proteins and decrease feed efficiency by 5–15% depending upon the livestock species and processing of the rations. In some areas of Africa, special processes are used to prepare the tannin sorghums to improve their food properties. Tannin sorghums bind enzymes during brewing of sorghum beer and additional malt is required.

The tannin sorghums are potent sources of antioxidants. Bran fractions and extracts from them have significantly higher oxygen radical absorbance capacity (ORAC) levels, a measure of antioxidant strength, than most fruits and vegetables (Table 2). Bakery products containing this bran have increased fiber content, higher antioxidant potential, and attractive natural brown or chocolate color. Tannin sorghums can also be transformed into excellent whole grain snacks by extrusion. The extrusion process significantly reduces the degree of polymerization of tannins, which may be beneficial in human foods.

Table 2 ORAC[a] levels in sorghum brans and extracts relative to common fruits

Sample	*ORAC[a] (DM basis)*
Black sorghum bran	1008
Sumac sorghum bran	3120
Tannin sorghum bran	2400
Blueberries	87–873
Strawberries	356–400
Plums	452–600
Grapes	100
Watermelon	15
Orange	80–152
Extracts	
Sumac sorghum bran	11 200
Grape skin	6124
Red wine concentrate	3200
Vitamin C = reference	5000

[a] ORAC, oxygen radical absorbance capacity, is a measure of antioxidant potential measured in μmol TE g^{-1}, using fluorescein as a probe.

Uses of the Grain

Food Uses

The major categories of traditional foods are fermented and unfermented flat breads, fermented and unfermented thin and thick porridges, steamed and boiled products, snack foods, and alcoholic and nonalcoholic beverages (Figure 2) (*see* **Cultural Differences in Processing and Consumption. Maize**: Foods from Maize). Worldwide, the most popular unfermented flat breads from sorghum are “roti” in India and tortillas in Central America. For roti, a portion of the flour is gelatinized, mixed with more flour and warm water, and kneaded into a dough, which is shaped into a circle, and baked on a hot griddle. For tortilla production, whole sorghum is lime-cooked, steeped overnight, washed, stone ground into “masa,” shaped into thin circles, and baked on a hot griddle (Figure 2d). Sorghum and maize blends are often used in Salvador, Nicaragua, Guatemala, and Honduras. Food-type white sorghums (Figure 2a) lighten the color and decrease the off-flavors in many food products.

The most popular fermented breads are “injera,” “kisra,” and “dosa,” consumed in Ethiopia, Sudan, and India, respectively. About 80% of the Ethiopian sorghum is used for production of injera (Figure 2i). The sorghum flour is mixed with water and a yeast starter from a previous batch of injera. After fermentation for 24–48 h, the batter is poured onto a greased pan for baking. The resulting product is a flexible, large diameter pancake-like bread containing uniformly distributed fish eyes (air bubbles). It is moist and retains its flexibility for 2–3 days. Dosa is consumed in India and is produced from a mixture of black gram, sorghum, and rice flour. It is used as a wrap for vegetables, sauces, and other foods.

Porridges are popular foods from sorghum (Figure 2g). The pH of porridges vary from acid to neutral to alkaline depending upon the region or country. “Tô” is an unfermented stiff porridge cooked in alkali in Mali, cooked in acid in Burkina Faso, or

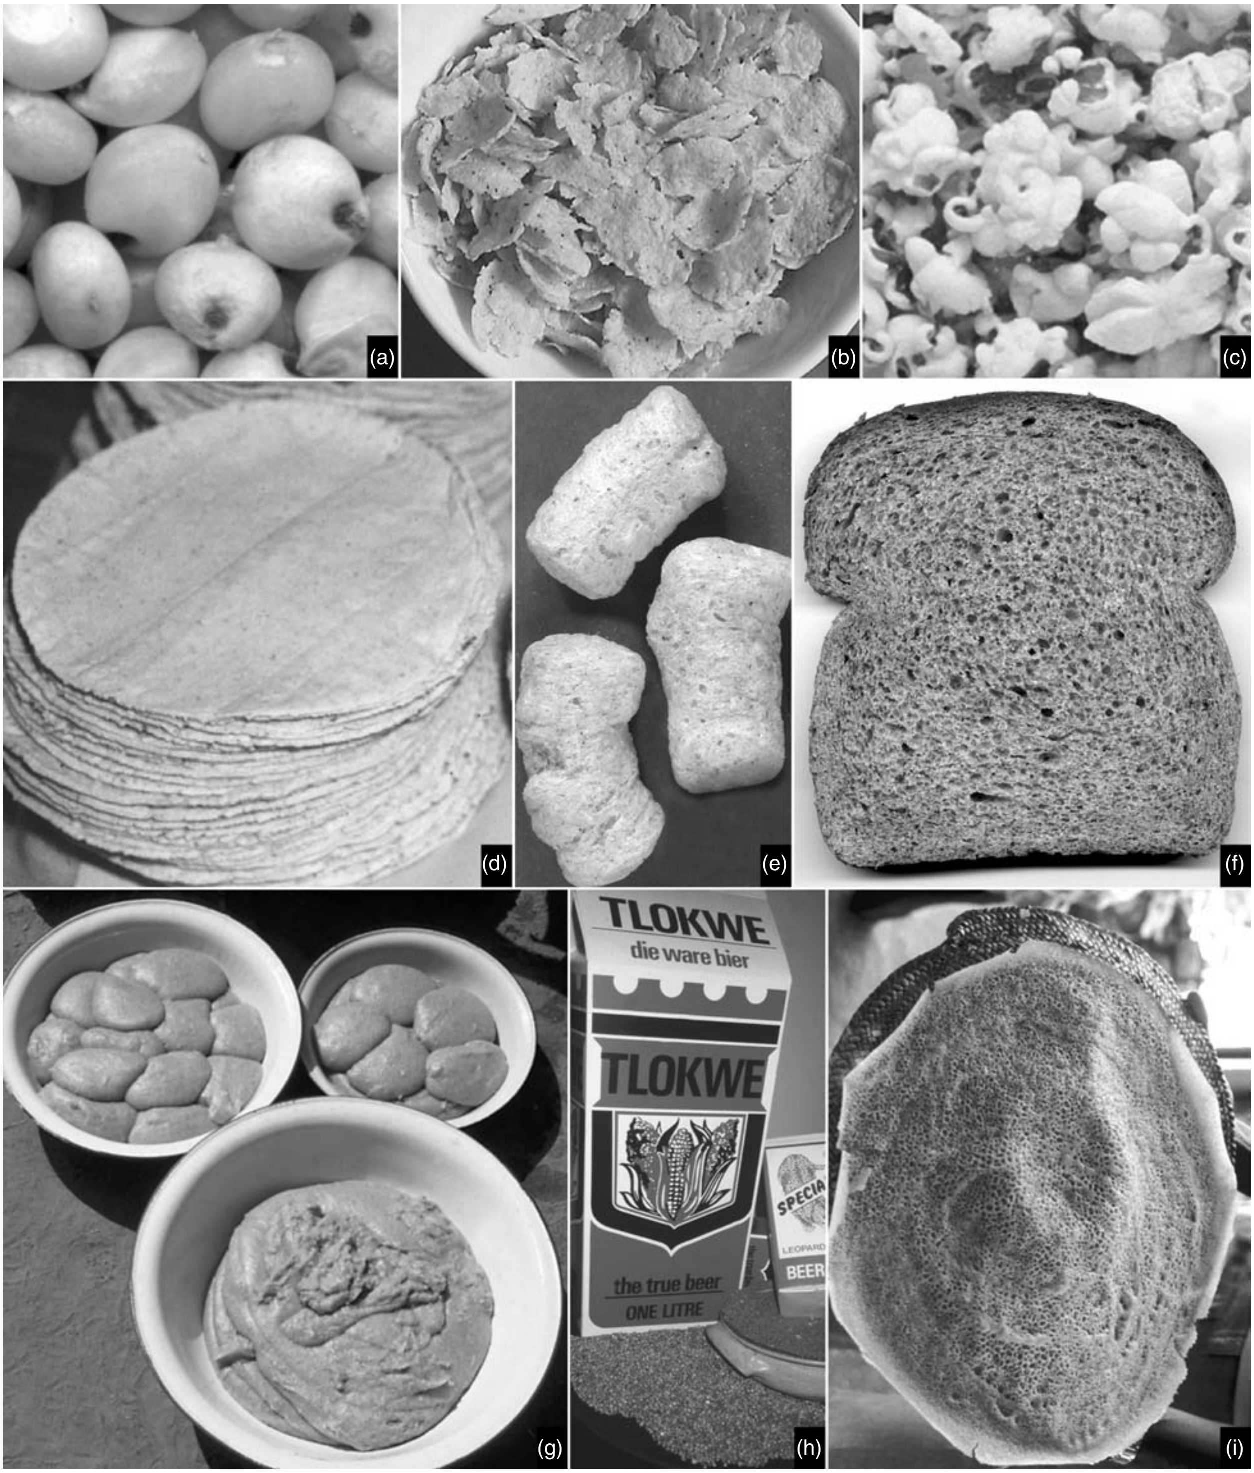

Figure 2 Traditional and processed foods prepared using sorghum. Note: (a) = white, food-type sorghum; (b) = flakes after whole grain was tempered, steamed, rolled, and toasted; (c) = air-popped sorghum; (d) = tortillas after whole grain was nixtamalized, washed, ground, formed into disks and baked; (e) = collets, whole grain was extruded; (f) = wheat bread containing 1.5% tannin sorghum; (g) = stiff porridge from sorghum after de-hulling, milling into flour, and cooking with water; (h) = opaque beer prepared from sorghum and malted sorghum; (i) = “injera” prepared from sorghum after decortication, milling into flour, mixing with water, natural fermentation, preparation of a slurry, and baking on a griddle.

fermented and cooked. Decorticated sorghum flour is cooked in water acidified with tamarind juice or water made alkaline with the leachate of wood ashes (potash). Popular fermented porridges are "ogi" and "nasha," widely consumed in West and East Africa, respectively. Whole sorghum is soaked in water and allowed to ferment for 2–3 days. The wet grain is crushed in a slurry of water and sieved to remove the bran. The fine particles are allowed to ferment longer. Excess water is decanted and the resulting slurry cooked in water or milk to make thin or thick porridges. Porridges are consumed with sauces prepared from vegetables, fish or meat, grain legumes, amaranthus leaves, and other materials.

For couscous production, sorghum flour is kneaded with enough water, ~30%, to form agglomerates. The wet flour is forced through a coarse screen to form large particles, which are steamed. The cooked product is consumed with a sauce or milk. In some cases, the particles are dried after steaming and used as one of the true convenience foods in the Sahelian zone of Africa. Decorticated sorghums are often cooked like rice.

Alcoholic beverages are produced from malted sorghum (Figure 2h). The high-solids beer is sour, alcoholic, pinkish, and effervescent. The fermentation time is short and the beer is drunk while actively fermenting. The beers vary from sweet to very sour; alcohol and solids contents vary. The most common type in southern Africa, called opaque beer, undergoes souring and yeast fermentation.

Sorghum processing into food is a tedious, time-consuming chore done by the housewives several times per week. There are very few processed foods that meet the convenience, taste, flavor, and texture requirements of urban consumers. Grain obtained in the markets is mixed and usually contaminated with sand, trash, and damaged grains. In some areas, value-added sorghum grain is processed into profitable products for sale in urban areas and local markets. The major challenge is to obtain a consistent supply of good-quality grain for processing.

Sorghum grits, meal, and flour can be used alone or mixed with wheat flour to produce an array of baked goods (Figure 2f). Sorghum does not contain gluten. Thus, the amounts of sorghum flour in the blends depend on the quality of the wheat flour, baking procedure, formulation, and quality of the baked products desired. New food-type sorghums that produce excellent yields of flour with a bland flavor and light color are available. They can be used to extend wheat-based products without affecting flavor. Sorghum can be puffed, popped, shredded, and flaked to produce ready-to-eat breakfast cereals (Figures 2b and 2c). Extrusion of sorghum produces acceptable snacks (Figure 2e) and precooked products.

Milling

For production of most traditional foods, the pericarp is removed by decortication, before it is milled into flour (*see* **Cultural Differences in Processing and Consumption. Maize**: Foods from Maize). To decorticate, the grain is usually washed, placed in a wooden mortar, and pounded vigorously with the wooden pestle. The abrasive action separates the pericarp from the kernel at the mesocarp. Grain with thick pericarp, hard endosperm, and spherical shape are preferred because they are easier to mill. A thin pericarp requires 1.5–2 times more time to decorticate. The bran (pericarp) is separated from the grain by washing with water or by winnowing the sun-dried grain. Most sorghums are decorticated to remove 10–30% of the original grain weight. The decorticated kernels are reduced into flour by pounding in the mortar and pestle, with stone mills, or by electric or diesel-powered attrition mills. Flour is sieved to obtain fractions with an acceptable particle size for specific products.

Commercial milling of sorghum is practiced in several countries. Sorghum is decorticated using mechanical decortication with rice-milling equipment or abrasive disks, followed by degermination and subsequent sieving. The decorticated material is then milled, gravity separated and sieved to produce low-fat grits, meal, and flour. In Botswana and South Africa sorghum is milled using abrasive decorticators followed by grinding the grain using hammer-mills or attrition mills. In India, sorghum is cleaned and milled using a stone mill followed by sifting to remove the bran, 1–3% of the original grain. The coarse flour is used for roti and related products. Milling of sorghum with wheat roller mills produces acceptable flour and other products. Small-industrial-scale roller mills produced in South Africa are used extensively to process maize, sorghum, and millet into flour and meal. The yields are quite high and the flour has good characteristics. Also, large sophisticated mills based on degermination and gravity separation of the milling fractions exist and produce highly refined grits, meal, and flour. In many areas of Africa, large-scale milling of sorghum has failed because of poor infrastructure and inadequate supplies of food quality grain.

Malting Sorghum and Brewing

Nonalcoholic beverages and extracts (*see* **Fermentation**: Foods and Nonalcoholic Beverages) are produced from malted sorghum, which has replaced

the malted barley extracts in Nigeria. Maltabella, Morvite, and a shelf stable opaque beer are popular products consumed in South Africa. Some companies produce ground sorghum malt for sale to consumers who prefer to produce traditional opaque beer for special festivals, weddings, and other occasions. In addition, powders containing pregelatinized maize grits, sorghum malt, and yeast allow consumers to produce beer by adding water and storing overnight.

Sorghum opaque beer In southern, eastern, and western Africa, sorghum malt is used for alcoholic and nonalcoholic beverages, weaning foods, and breakfast foods. Sour-opaque beers are produced commercially in southern Africa. Opaque beer is produced following the basic steps of the traditional process, which involves malting the sorghum, converting the cooked sorghum and maize grits into fermentable sugars, souring the mash, and finally fermenting the sugars into alcohol. The beer is packaged in vented cartons (Figure 2h) or transported to beer halls in stainless steel tanker trucks. The beer is drunk while actively fermenting.

Opaque beer was the first large-scale, industrial process of sorghum in Africa. Industrial enzymes replace sorghum malt to convert the cooked, soured grits of maize or sorghum into fermentable sugars. The color of the beer has become lighter, due to a greater use of maize as adjunct, and consumption of opaque beer is decreasing because consumers prefer lager beer.

Large commercial malting operations steep, germinate, and dry the malted sorghum for the breweries. Malting requires 4–5 days and 15–20% of the initial weight is lost in respiration, rootlets, and shoots. Sorghum malt is produced at 23–25°C during steeping and germination. Malting does not modify the cell walls of sorghum. Special varieties are grown for malting that produce malt with higher diastatic and other malt enzymes. Tannin sorghums are treated with formaldehyde and or alkali to limit the effects of tannins on diastatic or malt enzymes.

Lager beer (clear beer) Breweries in Africa and Asia use sorghum grits as an adjunct in brewing lager beer. In Nigeria, sorghum and maize are used to produce lager (clear beer) without barley malt. Nigerian breweries produce clear beer from a combination of malted sorghum, ground whole or decorticated sorghum, and/or maize grits with commercial enzymes to convert the starch to fermentable sugars. The quality of clear beer is good; the taste differs from barley malt beer. The modern industrial brewing of beer in Nigeria uses ground whole sorghum treated with commercial enzymes followed by filtration to remove the solids and then fermentation into alcohol. Sorghum malting is a costly process in terms of time with dry matter (DM) losses of 15% or more. The use of ground whole sorghum is a recent innovation, which requires a more efficient filtration procedure. Sorghum is preferred over maize since it has reduced oil content, a thin pericarp, and bland flavor.

Industrial Uses

Sweet sorghums contain 20–30% sugar in the juice which is crushed from the stalks, clarified, and concentrated into an amber sorghum syrup (molasses) that is a popular product in the southern US. It has a strong flavor and is sometimes blended with cane syrup.

Sorghum grain and/or sweet sorghum biomass are used for ethanol production. Yields of 182-proof alcohol ($387\,\mathrm{l\,t^{-1}}$) from sorghum grain are comparable with maize ($372\,\mathrm{l\,t^{-1}}$). The commercial technology to ferment sweet sorghum biomass into alcohol has developed in Brazil. Sorghum grain is a good substrate for industrial and beverage alcohol where it competes with maize and other sources of starch. Several alcohol plants in the US, India, and other countries use sorghum as an adjunct for alcohol production depending upon availability and cost. In China, a distilled alcoholic beverage from "kaoliang" (sorghum) is exported. It has a unique flavor and aroma and is high in alcohol content.

Sorghum flour is used in adhesives, building board, ore refining, and metal casting as an inexpensive source of starch. The sorghum is dry-milled to remove the pericarp and sometimes converted into acid-modified dextrins. Binders that strengthen the durability of pellets for livestock feed are made from sorghum.

Sorghum is wet-milled to produce starch in Sudan and India. Sorghum starch has properties similar to maize starch. Commercial wet milling of sorghum in the USA was discontinued in the 1970s due to poor economics.

Nutritional Value

Sorghum has proximate composition, amino acid contents, and nutritional value similar to that of maize. However, due to its lower fat content, sorghum usually has a slightly lower gross, digestible, and metabolizable energy. Lysine and threonine are the first and second limiting amino acids. The tryptophan content is higher than that in maize. High-lysine cultivars contain ~50% more lysine and promote better weight gains in weaning rats.

Fermentation, malting, and other processing methods significantly improve its nutritional value.

Proteins in sorghums are 76–82% digestible. This is ~5% less digestible than proteins from maize and other cereals as determined by *in vivo* studies using swine, poultry, and cattle. Proteins in sorghum were reported to be 20–50% less digestible than maize by the *in vitro* pepsin digestion test. This is based on the reduced digestibility seen when the sorghum was cooked as a gruel without stirring and fed to protein-malnourished, ill children. Extrusion cooking of sorghum eliminated the reduced protein digestibility in these children. Over the centuries, millions of Africans and Indians have been nourished by sorghum foods. Proper processing of sorghum yields foods with high digestibility and nutrient values.

Livestock Feeds

Sorghum is an excellent feed for livestock and companion animals. The feeding value of sorghum for livestock species is generally considered 95% or more of the feeding value of yellow dent maize. Tannin sorghums have 85–95% the feeding value of maize. Sorghum use can result in savings because it is often less expensive than other grains, even when more grain has to be fed.

Sorghum must be properly processed to enhance its digestibility. Sorghum can be dry rolled, steam rolled, cooked with steam, and flaked into thin flakes, micronized and flaked, roasted, ground, and tempered with water up to 30%, stored under aerobic conditions, or ground or rolled. The two most widely used processes are grinding and steam flaking. Sorghum is hammer-milled or attrition-milled into meal and coarse particles. Steam flaking is used in large feedlots where grain is a major part of the rations.

Grinding, steam flaking, micronizing, reconstitution, and popping are used to prepare sorghum grain in beef cattle feedlot rations. Grinding, rolling, crushing, and pelleting are used for poultry and swine feeds. Dairy cattle utilize steam flaked or roasted sorghum grain efficiently and protein content of the milk is enhanced. The light color and bland flavor of the white-food sorghums are advantages, when color is important in pet or companion animal feeds.

Future Prospects

Sorghum will for many centuries continue to be utilized as food, feed, and industrial products. This will be driven by sorghum's robust agronomic characteristics and good nutritive, processing, and organoleptic properties. Development of reasonably priced, convenience foods containing sorghum will increase the demand for food sorghums. An example of a niche market for sorghum is as an nutraceutical ingredient containing antioxidants. However, decreasing consumer preference for sorghum-based foods and beverages is likely to continue for those who have increased purchasing ability.

Introduction

World soybean production is ~183.4 million tons (Mt), with the United States accounting for 43% of the total (Table 1). The three largest producers have shown increasing production during the past 25 years (Figure 1). The increased production in Brazil and Argentina within the past five years has been dramatic.

Soybean oil comprises ~30% of the global consumption of vegetable oils and soybean meal accounts for ~70% of the global protein production. Soybean oil consumption has been under considerable pressure from canola oil and olive oil. These latter two oils also claim some health benefits.

Table 1 World soybean production (2001/02)

Country	*Production (Mt)*
United States	78.6
Brazil	43.5
Argentina	29.5
China	15.1
India	5.4
Paraguay	3.1
Other	8.2
Total	183.4

Origin

The genus *Glycine* (Willd.) belongs to the family Fabaceae, subfamily Papilionoideae, tribe Phaseoleae, subtribe Glycininae. The genus *Glycine* is composed of two subgenera, *Glycine* (perennials) and *Soja* (annuals). The proposed origin of the genus *Glycine* is given in Figure 2.

The linguistic, geographical, and historical evidence suggests that the annual soybean [*Glycine max* (L.) Merr.] emerged as a domesticated crop during the Zhou dynasty in the eastern half of northern China. An alternative hypothesis, based upon the center of genetic diversity, suggests that the soybean was domesticated in the Yellow River or Yangzi

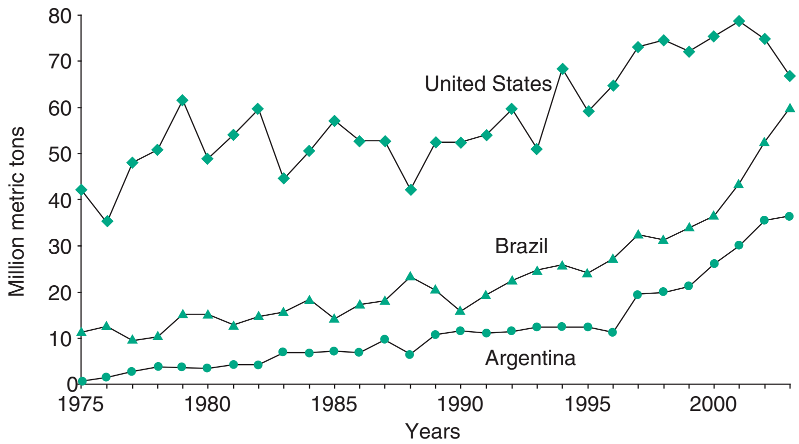

Figure 1 Soybean production of the United States, Brazil, and Argentina from 1975 to 2003.

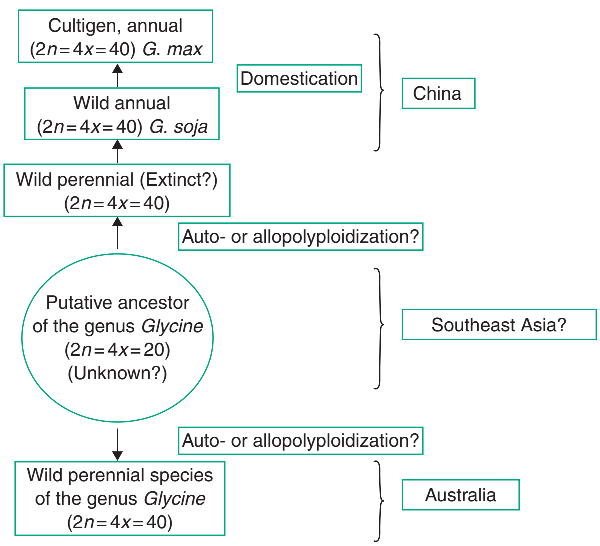

Figure 2 The origin of the genus *Glycine*. (Courtesy of Dr. T Hymowitz.)

valleys of central or southern China. Domestication of the soybean took place ~1500–1100 BC, or perhaps earlier. Soybeans were probably grown in the Korean peninsula as well as central and south China by the first century. From about the first century AD to the Age of Discovery (fifteenth to sixteenth century) soybeans were introduced throughout Southeast Asia. Traditional soy food included "miso," "tempeh," "tofu," and soy sauce. Soybean was introduced into Europe before 1737 and was introduced into North America, from China via England, in 1765.

Germplasm Collections

Major *Glycine* germplasm collections exist in Australia, Brazil, China, Germany, India, Indonesia, Japan, Russia, Republic of Korea, Taiwan, Ukraine, and the United States. Many other smaller but important collections exist throughout Asia, and Europe. The *G. max* germplasm collections are given in Table 2, the *G. soja* collections (Table 3), and the *Glycine* perennial collections (Table 4).

Gene Pools

The concept of gene pools is useful to plant breeders because it guides them in selecting germplasm to use in hybridizations for plant improvement. The genus *Glycine* has only a primary gene pool and a tertiary gene pool (Figure 3). The primary gene pool consists of *G. max* cultivars, land races, and the wild annual *G. soja*. Cross-pollination within the primary gene pool results in regular chromosome pairing and fertile progeny. The secondary gene pool is not known. The tertiary gene pool consists of the wild perennial *Glycine* species. Cross-pollinations between members of the primary and tertiary gene pools are not possible or require embryo-rescue techniques.

Germplasm Diversity

Within the genus *Glycine* subgenus *Glycine*, there are 22 recognized wild perennial species, and within the subgenus *Soja* are two species (Table 5). These perennial species are diverse morphologically, cytologically, and genomically, and are mostly endemic to Australia (Table 5).

Germplasm Utilization

The practice of germplasm selection and utilization traces to the Chinese farmers who selected desirable phenotypes (plants) to use for seed in the next planting. Desirable changes could have arisen from natural cross-pollinations or mutations.

Plant breeders made sexual pollinations in soybean as early as 1927 in China and in 1902 in the United States by E E Evans. By year 2000, ~800 public cultivars in China, 100 public cultivars in Japan, and more than 600 public and 2000 proprietary cultivars in North America had been released. In addition, plant breeders in South America, Korea, and India had released a total of more than 400 cultivars.

The cultivated soybean is considered a quantitative short-day plant. This photoperiod sensitivity defines the area of adaptation as delimited by latitude. For convenience, in North America, cultivars have been classified into maturity groups based upon their responsiveness to photoperiod. This relatively narrow band of latitude, in which a soybean genotype is adapted, results in 13 maturity group

designations: 000, 00, 0, and Roman numerals I–X, from North to South. The few photoperiod insensitive cultivars that have been released have not been agronomically competitive with photoperiod-sensitive cultivars.

Germplasm Utilization – Perennials

The 22 wild perennial soybean species represent a reservoir of useful genes to improve the cultivated soybean. This includes resistance to soybean rust (*Phakopsora pachyrhizi* Sydow), soybean brown spot (*Septoria glycines* Hemmi.), powdery mildew (*Microsphaera diffusa* Cke. and Pk.), phytophthora root rot (*Phytophthora sojae* H J Kaufmann and J W Gerdemann), white mold (*Sclerotinia sclerotiorum* (Lib. De Bary)), sudden death syndrome (*Fusarium solani* (Mart.) Sacc.), tobacco ring spot (G L Hartman, personal communication), yellow mosaic virus, alfalfa mosaic virus, soybean cyst nematode (*Heterodera glycines* Ichinohe), and tolerance to certain herbicides and to salt, and are more amenable to tissue culture regeneration. Exploitation of the wild perennial species for soybean improvement has received renewed interest in recent years. The major impediment is the extremely low crossability and the need to use embryo-rescue techniques to obtain hybrid plants. Many interspecific hybrid combinations give weak, slow growing plants that are completely sterile.

Germplasm Utilization – *G. soja*

The *G. soja* accessions harbor many undesirable genetic traits, e.g., lodging, vining growth habit, susceptibility to biotic and abiotic stresses, lack of complete leaf abscission, pod shattering, and black seedcoat. Limited numbers of interspecific crosses between *G. max* and *G. soja* have been made in attempts to broaden the genetic base of *G. max* cultivars. Generally, introgression of favorable traits has not been successful. However, small-seeded cultivars, that have *G. soja* as one parent, have been released for sprouts or the fermented Japanese product "natto." One Russian cultivar that has a higher percentage germination under cooler temperatures has been released. The wild annual soybean is high in seed protein but low in seed oil.

Germplasm Utilization (North America) – *G. max*

The *G. max* accessions form the basis for modern soybean cultivar improvement programs. Ten plant

The data in this table were gathered from the database maintained by the International Plant Genetic Resources Institute (http://www.ipgri.org/) (verified 22 Nov. 2002). Some numbers were updated *via* direct contacts with the holding institutions. Number of accessions is reported by country and in some cases there may be more than one collection per country.

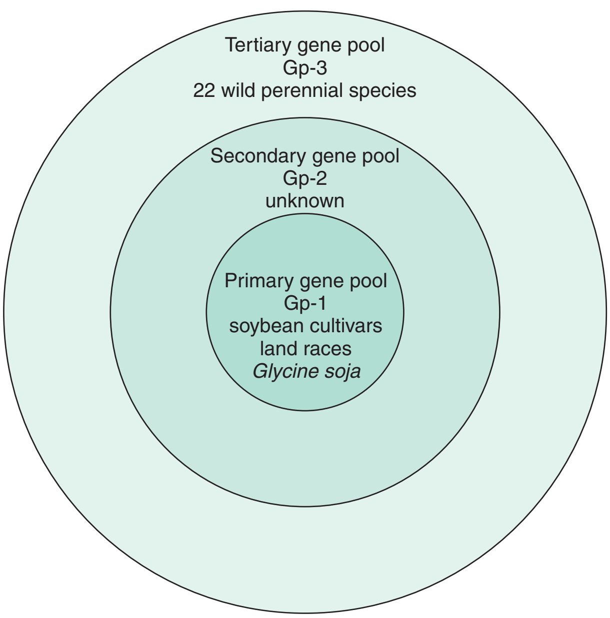

Figure 3 The gene pools of the soybean. (Courtesy of Dr. T Hymowitz.)

introductions (accessions) have contributed more than 80% of the North American maturity gene pool, and seven introductions contributed more than 80% of the southern United States maturity groups. Accessions have contributed the most to pest resistance. The most common method of gene transfer has been through backcrossing. For example, resistance to downy mildew (caused by *Peronospora manshurica*), to root rot (caused by *Phytophthora sojae* (Kaufmann and Gerdemann)), to bacterial pustule (caused by *Xanthomonas campestris* pv. *glycines* (Nakano) Dye), and root knot (caused by *Meloidogyne* spp.) has been incorporated into susceptible cultivars to develop near-isogenic resistant cultivars. Recently, accessions have played a prominent role as sources of resistance to brown stem rot (caused by *Phialophora gregata* Allington and Chamberlin) W. Gams and to cyst nematode. Another example includes the cultivar Kunitz; which is missing the antinutritional factor Kunitz trypsin inhibitor SBTI-A2 derived from a *G. max* accession (PI 157440) from South Korea.

The selection of parents used for soybean cultivar development is determined largely by the breeding objective and the germplasm available to use as parents. Direct cross-pollination of cultivars with germplasm accessions, followed by inbreeding and selection, generally has not contributed to the development of modern high-yielding cultivars. A topic of much discussion among soybean breeders is whether continued advances in cultivar development for seed yield, beyond the level possible with the domestic gene pool

of elite breeding lines and cultivars, can be achieved. The utilization of accessions in cultivar development might be successful if selection systems were known that could identify introductions that have good combining abilities with adapted genotypes. Two-parent crosses of "good" by "good" cultivars or elite experimental breeding lines, have been the most extensively used by breeders because of the higher probability of obtaining high-yielding cultivars.

Germplasm Utilization (Other Countries) – *G. max*

Unlike the North American genetic bases, the Chinese genetic base encompasses 190 ancestors that have contributed 80% to the parentage of the Chinese soybean cultivars. The genetic base of the Japanese cultivars has shifted over time. Before 1945, Chinese accessions were important as parents in Japanese cultivars. In the late 1950s, increasing numbers of North American cultivars and breeding lines were used as parents.

South Americans have relied extensively upon North American cultivars for direct release to farmers. In recent years, the South American breeding programs have released cultivars that are competitive with those introduced in North America.

Breeding

The first cultivar that originated as a selection made among progenies of controlled hybridizations was the cultivar Ogemaw released in 1902. Cultivar development in the United States initially was conducted by the USDA and state agricultural experiment stations. Now, in the main soybean-producing regions, private companies develop and release most of the cultivars.

Conventional soybean breeders follow a cycle of "crossing of parents" followed by "progeny evaluation and selection of parents" and "development of progeny for testing."

Breeding Objectives

The first step in cultivar development is to identify the characters that are important for commercial soybean production whether it is for feed, food, or industrial uses. Yield is the character of prime importance to the

farmer. Data from 1941 to 2000 of North American maturity groups 00–IV show that soybean breeders have increased seed yield ~1% per year. In China yield gains for soybean breeding programs were low before 1970. Since the 1980s yield gains between 1% and 2% per year have been realized.

In soybean, diseases, nematodes, and insects can reduce yields substantially. Generally in soybean breeding, tolerance to pests is not the objective, rather the emphasis is breeding for resistance.

Lodging resistance or standability is important for mechanical harvest, and plants that are not upright have decreased yield. Most earlier maturing cultivars are of indeterminate growth habit, while later maturing cultivars are of determinate growth habit. The short, determinate cultivars have better lodging resistance.

Pest resistance is of paramount importance in soybean-growing areas where diseases, nematodes, or insects are major problems. Most major soybean-1growing areas have one or more major pest problems. Breeding for pest resistance is dependent upon the prevalence and regularity of economic loss in each area.

Shattering resistance refers to the ability of a plant to retain its seed when mature. All modern cultivars have adequate resistance to shattering.

Seed Composition

Seed composition is becoming an important factor to consider in soybean breeding. Cultivars generally have ~40% seed protein and 20% seed oil. In most environments, if seed protein increases, seed oil decreases, and vice versa. Both food uses and industrial uses are creating greater demands for specialty use soybean such as soy milk and soy ink for printing. A number of breeding programs now focus on breeding specialty beans.

Soybean seed oil is the major vegetable oil among oil seed crops worldwide and modification of seed oil has received the most focus. Oil synthesis in the seed and seed fatty acid composition are largely determined by the maternal parent. The fatty acid content of conventional soybean cultivars is ~11% palmitate, 4% stearate, 24% oleate, 54% linoleate, and 7% linolenate. The desired variation in seed oil fatty acid composition was not found in the *G. max* or *G. soja* germplasm collections. Mutagenesis, both chemical and ionizing radiation were used to create a number of highly desirable mutations with modifications in individual fatty acids (Table 6). The modification of soybean oil and selection for superior agronomic traits has resulted in cultivar releases, e.g., Satelite, which has lower saturated fatty acids and lower linolenic acid.

Table 6 Mutations that either elevate or reduce soybean seed oil composition

Fatty acid	*Number of mutants*	
	Elevate	*Reduce*
16:0 (palmitate)	6	8
18:0 (stearate)	5	0
18:1 (oleate)	2	2
18:2 (linoleate)	0	1
18:3 (linolenate)	2	5

Industrial uses include soy ink for both black/white and color newsprint and as a major component of lubricants and gasoline for automobiles, trucks, buses, and marine engines.

Several vegetable-bean cultivars, known as "edamame," with improved agronomic qualities are available. Natto, a fermented product, soymilk, and soy protein isolates are important food uses of soybean. Tofu, a cheese-like curd for human consumption, has a high percentage of protein.

Other traits that are important in breeding cultivars include maturity, seed quality, seed emergence, herbicide tolerance, plant height, and resistance to mineral deficiencies and toxicities.

Specialty Cultivars

Breeding of specialty cultivars, especially cultivars with value-added traits, has been given increased emphasis in recent years. These include cultivars with altered seed composition for oil and protein quality and quantity, seed size and color, and growth habit, e.g., forage soybean. Specialty cultivars are used for soyfoods, industrial applications, and for feed. Parents used to breed specialty cultivars have added genetic diversity to the soybean gene pool.

Breeding Methodology

Soybean is a highly self-pollinated species and all cultivars are either pure lines (inbred lines) or mixtures of pure lines. All cultivars released today in the major soybean-growing areas of the world are the result of sexual hybridization followed by selection. The cyclic process of hybridization, inbreeding, and evaluation/selection form the basis for soybean cultivar development.

Breeding methods include pedigree, bulk, mass selection, single-seed descent, and backcross. Single-seed descent, also known as a modified pedigree method is favored by many soybean breeders, because it minimizes the number of years for cultivar development. Single-seed descent is well suited for generation advances (inbreeding) in off-season nurseries,

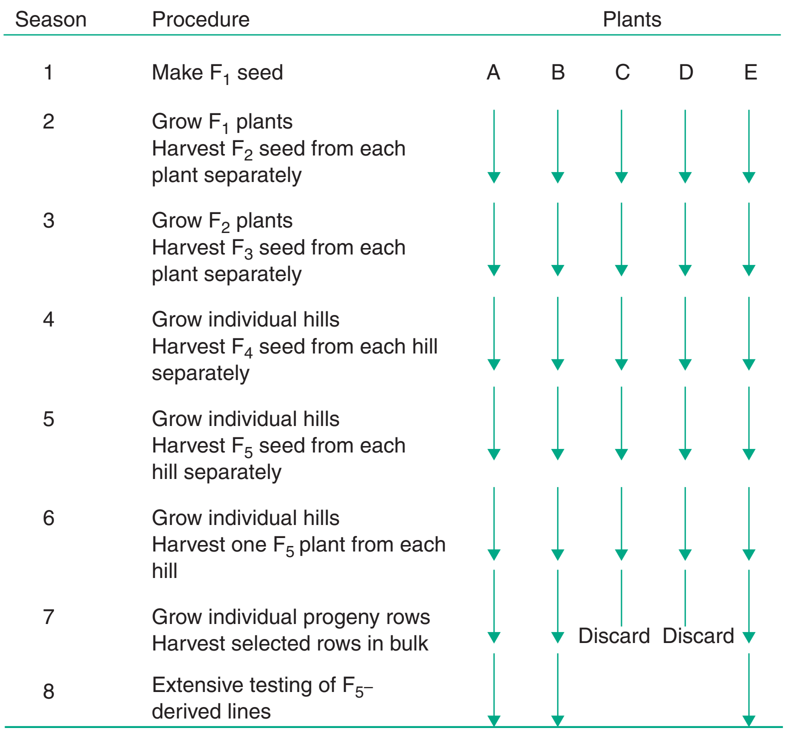

Figure 4 Example of a single-seed descent method. Variations include harvesting one pod, or only one seed to advance to the next generation. Harvesting one plant insures that all F_2 plants are represented in the final selection process.

e.g., Puerto Rico, Hawaii, Hainan Island (China) or South America, or in glasshouses (Figure 4).

The pedigree method is based upon selection among plants during inbreeding. The inability to make selections in off-season nurseries and glasshouses for important agronomic traits is a severe limitation.

The bulk method entails growing a population of plants, usually F_2 generation, harvesting all the seed in bulk, and planting a seed sample from the bulk harvest the next season. This procedure is repeated until the desired level of inbreeding (homozygosity) is achieved, then selection is initiated.

The mass selection method involves inbreeding plants selected on the basis of phenotype, compositing the seed without progeny testing, and inbreeding until the desired level of homozygosity is attained.

Early generation testing has been used to produce soybean cultivars. This method involves identifying desirable heterogeneous populations or lines from which superior homozygous individuals can be selected.

In North America, the USDA coordinates the regional evaluation of advanced breeding lines submitted by USDA scientists, Agriculture and Agri-Food Canada scientists, and state (United States) or provincial (Canada) agricultural experiment stations. These elite breeding lines are advanced to the Preliminary and Regional Tests. This testing program, from maturity groups 00 through VIII, enables breeders to evaluate breeding lines under a wide range of environmental conditions. Lines are usually entered only once in the Preliminary Tests, and then are either deleted or advanced to the Uniform Tests for a maximum of three years, if agronomic performance warrants further testing. The best publicly derived cultivars in each maturity group are used as check (control) cultivars in which to compare the elite breeding lines for seed yield, seed chemical composition, maturity, height, lodging, seed quality, and reaction to diseases and nematodes.

Hybrid Soybean

Soybean male sterility was reported in 1971. Since that time at least eight international patents on soybean sterility systems and hybrid seed production have been granted. There are five components that are crucial for the successful development of commercial hybrid soybean:

- Parental combinations that produce heterosis levels superior to the best pure-lines cultivars.
- A stable male-sterile, female-fertile sterility system.
- A selection system to obtain 100% female (pod parent) plants that set seed normally and can be harvested mechanically.

- An efficient pollen transfer mechanism from pollen parent to pod parent.
- An economical level of seed increase for the seedsman and growers that ultimately benefits the consumer.

Research results show that F_1 hybrid vigor (heterosis) does exist in soybean with the better hybrids yielding between 10% and 20% above the high parent. The major obstacle to commercialization of hybrid soybean is pollen transfer from the male parent to the pod parent. Considerable advances in insect-mediated cross-pollination are necessary before large numbers of hybrid seed can be obtained. Then hybrid combinations can be tested in multiple environments to assess hybrid vigor and to determine the potential for commercialization. Perhaps equally important for the commercialization of hybrid soybean would be the benefit of a technology protection system. Such a system when combined with "trait stacking" would benefit the seedsman, growers, and ultimately the consumer.

Genetics

Soybean is expected to have 20 linkage groups ($2n = 4x = 40$ chromosomes). The diploid progenitor of soybean has not been identified. The small size, large number, and similar morphology of the chromosomes have been deterrents to progress in soybean cytogenetics and genetics. However, a chromosome map based upon pachytene chromosome analysis has been completed.

Cytogenetics

Haploids can be produced in soybean, but the difficulty in production, e.g., unique mutants, and the low frequency has precluded their use in breeding. Polyploids rarely occur spontaneously but can be produced through chemical treatment, but are not suitable agronomically.

Addition aneuploids, especially primary trisomics, have been very useful to locate genes to specific chromosomes and all 20 unique primary trisomics are known. Soybean can tolerate addition aneuploids but surprisingly the occurrence of deficiency aneuploid plants has been low and they cannot be maintained.

Chromosome interchanges (translocations) have been studied cytologically and have been used to locate genes to specific chromosome arms. Chromosome inversions, both pericentric and paracentric, are found in accessions in *Glycine*. Inversions have not been used in linkage studies.

Extensive cytogenetic studies in the genus *Glycine* have been done with the perennial species. Because of the reservoir of desirable traits in the perennial species, active gene transfer programs from wild perennial species to the cultivated species are of paramount importance.

Soybean has been suggested to be an ancient polyploid based upon chromosome number, genome size, the identification of duplicate loci, high fertility levels (male and female) of primary trisomic plants, and the high levels of transmission of the extra chromosome through both male and female gametes. The duplicated genome(s) and duplicated genes in soybean have been reorganized through processes such as loss of duplicated segments, single-gene duplication via unequal crossing over, chromosome re-patterning, transposition, gene conversion, recombination, divergent evolution, and gene silencing. Collectively, the cytogenetic and genetic evidence supports the view that the cultivated soybean is a diploidized polyploid.

Qualitative Genetics

The soybean *Genetic Type Collection* maintained by the USDA is a comprehensive tabulation of qualitative genetic traits with gene symbols, phenotypic descriptions, source of mutants, and reference citations. Genetic mutations include resistance to fungi, bacteria, viruses, nematodes, insects, resistance or tolerance to herbicides, response to *Rhizobium*, time of flowering and maturity. Plant growth traits include stem, petiole, inflorescence, leaf form, pubescence type, and seed-coat structure. Genes are known that cause sterility, either complete or partial, of male and/or female gametes. Genes for response to nutritional factors, to pigmentation (seed, leaves, flowers, pod, and pubescence) are known. Many mutations that affect isoenzymes and proteins are documented. Qualitative genetics have played a major role in plant breeding programs for genes for pest resistance.

Molecular Genetics

The development of a soybean molecular genetic map based upon DNA sequence polymorphisms initially relied upon restriction fragment length polymorphisms (RFLP). Additional classes of DNA markers were developed after the advent of the polymerase chain reaction (PCR) technology. They include simple sequence repeat (SSR) markers, random amplified polymorphic DNA (RAPD) or arbitrary primer PCR (AP-PCR) markers, DNA amplification fingerprinting (DAF) markers, amplification fragment length polymorphism (AFLP) markers, and single-nucleotide polymorphism (SNP) markers. The integration of the classical genetic map into the molecular

genetic map, and the association of the markers to their respective chromosome is under development.

The use of molecular techniques in soybean to locate quantitative trait loci (QTL) has received much attention. This type of marker-assisted selection (MAS) has been used to locate seed composition traits, reproductive traits, time of flowering and maturity traits, response to nutritional factors, etc.

Transformation

Foreign genes can be delivered into soybean via *Agrobacterium*, particle bombardment, and electroporation. The *Agrobacterium*-mediated floral dipping method and the pollen-tube pathway transformation method have not been successful in soybean. Most of the gene transfer methods are tissue-culture based, requiring regeneration of whole plants from transformed cells. Because of the lack of efficient regeneration and transformation procedures, soybean remains recalcitrant for genetic transformation. In addition, the use of *Agrobacterium*-mediated transformation systems shows considerable genotype specificity.

A commercial success with transformed soybean has been with glyphosate herbicide (Roundup®) tolerance. Roundup Ready® soybean cultivars were grown on ~70% of the acreage in 2002 in the United States and Argentina and have provided the farmer with a new weed control system. At present, Roundup Ready® cultivars cannot legally be grown in Brazil.

Future Prospects

Germplasm collections have continued to expand. Many acquisitions are land races or local cultivars, that are being replaced by newly released cultivars. The addition of new wild perennial species continues and the "discovery" of new species seems likely.

Qualitative genetic mutants are continually being added to the USDA's *Genetic Type Collection* and are available to all soybean scientists. Some are of spontaneous origin but many are from mutation programs, e.g., seed fatty acid mutants. A few transgenes (from genetic engineering research) are available.

Gene discovery, through the use of expressed sequence tags (EST) will permit the identification of differential patterns of gene expression. Genome sequencing is the cornerstone of functional analyses. Functional genomics is the process of generating, integrating, and using information from genomics, gene expression profiles (microarrays and chips), and proteomics. This will permit large-scale genotyping of plants in order to understand gene function. The end result will be improved soybean cultivars for food, feed, and industrial uses.

Soybean (*Glycine max* (L.) Merr.) is the world's most important oilseed crop. Cultivated soybean originated in China ~5000 years ago, and was originally used as a forage crop when imported into the United States ~80 years ago. During the late 1940s and 1950s soybean became more valuable as an oilseed crop in the Midwest when oil extraction facilities were built to separate the oil from the meal in the seed. Soybeans now are typically grown as an annual summer crop with the ability to fix nitrogen in association with the bacteria *Bradyrhizobium japonicum*. This nitrogen replaces the need to use nitrogen fertilizer on the crop and, therefore, reduces the cost of production.

Soybean production in the United States has been at or near record levels in recent years. The upper Midwest produces 70–90% of the soybeans in the United States. Iowa and Illinois are the leading producers, but production spans 29 states east to west from Delaware to Nebraska, and north to south from the Dakotas to Texas. In 2002, the United States accounted for ~38% of the world's soybean production annually, followed by Brazil (28%), Argentina (17%), and China (9%). This article considers how soybean growers are managing the crop to produce high yields, how lack of soil moisture limits productivity, and how genetic and environmental factors affect the chemical composition of the soybean seed, which determines its value in the marketplace.

Managing the Crop for High Yield

Planting Options

Soybean crop management includes all activities of crop production that are controlled by the producer.

These activities include everything from soil tillage prior to planting through harvesting and storage. Today about one-fourth of the soybeans in the United States are planted without prior soil tillage (no till). The majority of the soybean crop is planted into soil that has received minimum tillage, which leaves variable amounts of residue on the soil surface to reduce soil erosion by rainfall. Studies have shown that soybean grain yield differences are minimal when no-till and minimum tillage systems have been compared.

Soybean is usually grown as a sole crop (one crop per year on the same field) and is planted in the spring of the year in temperate areas. Temperature of the soil determines the planting date of soybean. Soil temperature near the seed must be 8–10°C before soybean seed will germinate. Therefore, soybean is planted between April and June in the Midwestern United States, and most other northern latitude production areas in the world. In temperate areas of the southern hemisphere, soybean is planted between October and December. Tropical and subtropical production areas are able to plant any month of the year if water is available from rainfall or irrigation, because soil temperatures in these regions usually do not limit soybean plant growth.

Soybean yield responds to the date of planting and row spacing. Early planting from late April to mid-May results in the highest grain yield of soybeans grown in Iowa. June plantings result in lower yields because of a shorter growing season. The machine used and method of planting control row spacing of the soybean crop. A grain drill can plant seeds in narrow rows, 25 cm or less apart. A typical row crop planter can range from 25 cm to more than 100 cm between rows. In Iowa, intermediate row spacings (25–75 cm) produce the highest soybean yields. If the seed is planted by hand, row spacing may be determined by the previous crop. In Thailand, for example, soybean is frequently planted following rice harvest. So the soybean is hand-planted adjacent to the rice plant stubble.

Seeding rate also is an important management variable for high yield. Seeding rate is the number of seeds sown per area of land. The loss of plants during germination or later in the growing season due to insects, diseases, weed competition, or other stresses can amount to 15–25% of the seeding rate. Harvest population is the most important plant density measurement, since this represents the plant stand that produces the grain yield. If moisture and fertility are adequate, and the stand loss is normal, the optimum seeding rate is ~400 000 plants per hectare. However, soybean is very adaptable to different growing conditions and can produce similar grain yields across a wide range of seeding rates. In Iowa studies, soybean yield was not significantly different for harvest populations between 280 000 and 500 000 plants per hectare.

Planting depth of the seed is also an important management consideration. The recommended planting depth is 3–5 cm below the soil surface. However, exceptions occur with different soil types, moisture content of the soil, and soil temperature at seeding depth. Cool, light-colored soils are usually slow to warm to the desired temperature for germination, so planting the seed closer to the surface is desirable. Seeds planted less than 3 cm from the soil surface, however, might not obtain sufficient moisture to germinate. Darker-colored soils tend to warm more rapidly than light-colored soils. When soybean seed is planted into no-till environments, the soil is frequently covered with light-colored crop residue, which reflects radiation and slows soil warming. In such conditions, emergence may be delayed and plant stands reduced due to insect or disease damage to the seed or seedling. Deeper planting might be justified to place the seed closer to moisture, if the upper 5 cm do not contain sufficient moisture for seed germination. Planting soybeans more than 5 cm below the soil surface, however, may lead to poor stands.

Pest Management

Pest control during the growing season is critical to achieve maximum grain yield. Weed control may be achieved by crop rotation, mechanical cultivation, or herbicide application. Herbicides have been the most popular method of weed control for many years. Recent developments in molecular genetics have resulted in the development of herbicide-resistant soybean varieties that allow the soybean plants to survive applications of the herbicide glyphosate. This development allows the producer to apply glyphosate over the soybean crop and control most weed species without damaging the soybean plants. This technology has provided the producer with a simple way to control weeds, and ~80% of the soybean area in the United States is sown with glyphosate-resistant soybean varieties. In Argentina, between 90% and 95% of the area is sown with cultivars that are resistant to glyphosate herbicide.

Disease control in soybean also is essential and can be achieved with a combination of genetic resistance, crop rotation, pesticides, or biological control. A number of disease organisms can attack the soybean plant during the growing season. The damage caused by diseases may affect the ability of roots to absorb moisture and nutrients, or limit leaf area development, resulting in reduced yield potential. Genetic

resistance is the preferred method to control the impact of disease infestations, since chemical methods must be timely and often repeated.

Insects may also cause damage to the soybean crop. The severity of insect damage depends on the stage of plant growth when damage occurs and the intensity of the infestation. Damage to the roots, leaves, stems, and pods are common and may reduce the ability of the plant to function properly. Mechanical damage may open avenues into the plant for disease pathogens to enter and cause additional plant stress. The intensity of insect damage to a soybean crop varies from year to year due to differences in environmental conditions, the reproductive capability of the insect, and whether the insect is a vector for viruses such as soybean mosaic virus or bean pod mottle virus.

The soybean cyst nematode is the most severe pest to the soybean yields in the upper Midwestern United States. Other nematode species attack soybeans in other production areas of the country. Visual symptoms of soybean cyst nematode feeding usually do not occur until late in the growing season when leaves turn yellow prematurely. Unless a soil sample is tested for nematode eggs, the producer might not be aware of a nematode problem. If the nematode egg population in the soil is high, the yield loss may be 50% or greater. Crop rotation will interrupt the multiplication of cysts, but genetic resistance is the most successful control for this damaging pest.

Harvesting Considerations

Soybean harvesting and storage are also management practices, which must be carefully controlled to ensure high yields. Unless care is taken to adjust the harvesting combine correctly for the environmental conditions and seed size, seed will be lost unnecessarily during the harvesting process. Slower ground speed of the combine will reduce harvest losses. Many producers store the soybean grain after harvest for sale at a later date. In such cases, yield can be lost during storage due to seed respiration, physical deterioration, or diseases. Therefore, care must be taken to store the grain in clean dry conditions so the seed quality does not deteriorate, and quantity remains stable until the moment of sale.

Soybean crop management for high yield is very complex and these management practices challenge the producer, but they must be integrated into a production system to produce the maximum potential genetic yield of each variety grown. Failure to carry out all the recommended crop management practices may result in reduced yield and profit for the producer.

Managing Water Use for High Yield

Despite proper soil testing, seedbed preparation, cultivar selection, weed control, and other management options, biotic, and abiotic stresses can result in partial or near-total failure of a soybean crop. On a worldwide basis, an adequate and timely water supply is the condition most likely to limit yield of soybean or other crops. In this section, we will review the importance of water supply to soybean growth and yield, and discuss management options for ameliorating yield loss due to drought.

A useful framework of evaluating soybean grain yield ($\mathrm{kg\,ha^{-1}}$) in water-limited environments is that grain yield (Y, $\mathrm{g\,m^{-2}}$) is the product of three largely independent entities according to eqn [1]:

$$Y = T \times \mathrm{WUE} \times \mathrm{HI} \qquad [1]$$

where T is cumulative crop transpiration from emergence to physiological maturity ($\mathrm{l\,m^{-2}}$), WUE is the water use efficiency (g plant mass $\mathrm{l^{-1}}$ water transpired), and HI is the harvest index ($\mathrm{g\,g^{-1}}$) (proportion of grain mass to total shoot mass at maturity). Management strategies or genetic traits that increase any of these three determinants of grain yield likely will increase the yield under drought conditions. Conversely, if transpiration, WUE, or harvest index are not affected by management strategies or by a genetic trait, the trait is unlikely to have an impact on yield in water-limited environments. Each of these determinants will be examined for ways in which they may be improved, through either genetic traits or crop management.

Increasing Water Use for Transpiration

Equation [1] indicates that yield is proportional to the amount of water transpired by the crop, provided that WUE and harvest index remain fairly constant. Several management strategies can play important roles in increasing the amount of water available for crop transpiration. For some soils, soil–water storage and infiltration can be increased by deep tillage in the fall and by residue management. Old root channels and crop residue from no-till systems increase water infiltration and water-holding capacity of soil and function as a mulch for the soil surface, which decreases evaporative losses. Decreasing tillage by sowing soybean in a stale seedbed conserves a considerable amount of soil moisture that can be utilized during later stages of crop development. In Iowa, an estimated 20–30 mm of soil moisture is lost from the seed zone during traditional spring cultivations compared to less than 6 mm lost from a no-till system. Evaporation of water from the soil surface may account for up to one-half of the total amount of

evapotranspiration for a soybean crop. Rapid canopy closure, by using narrow rows and high population densities, decreases evaporative losses from the soil surface, which increases the amount of water available for crop growth and yield.

One determinant of the quantity of water available to a crop is rooting depth. If the rooting depth (D) is known for a particular site, then the total amount of available soil water can be estimated as $D \times 0.13$. The value of 0.13 was derived from an extensive survey of soils across the US, and represents the difference in the volumetric water content of soil at field capacity and when the soil is very dry and plants are dead or dormant. This relationship was similar across all soil textural classes except those in which the sand content was greater than 0.55. For sandy soils, the difference between the volumetric water content at field capacity and when plants were dead and dormant was considerably less than 0.13.

As a soil begins to dry due to evapotranspiration, crop photosynthesis and other physiological processes are generally unaffected until ~0.65 of the available soil water is depleted. A critical water deficit, defined as the volumetric water content at which physiological processes and yield begin to decrease, can be estimated from eqn [2]:

$$\mathrm{CWD} = D \times 0.13 \times 0.65 \qquad [2]$$

where CWD is the critical water deficit (mm) and D is the rooting depth (m) of the crop. The difference between rainfall and potential evapotranspiration is used to estimate the crop water deficit for each day. By summing the daily water deficits, one can evaluate when water deficit approaches a critical value for a specific site.

Figure 1 shows the long-term averages of the 27 day running sum of water deficit for each day of soybean production at four sites in the United States. Although these sites are geographically and climatologically distinct, the average water deficit exceeds 110 mm in each case. Avoiding a critical water deficit in an “average year” at these sites would require a rooting depth of at least 1300 mm (eqn [2]). For many sites, roots are unable to reach such depths. For example, in the mid-southern US, irrigation is generally scheduled when the critical water deficit reaches 37–50 mm, which corresponds to a rooting depth of 438–592 mm.

Genetic differences among soybean lines offer an important means of increasing rooting depth in specific environments. Variation has been found in soybean for deeper root penetration in soils with high aluminum content. High soil aluminum is generally associated with low soil pH and estimated to affect ~40% of the arable land worldwide. Although the upper 15–20 cm of a soil may be limed to decrease soil aluminum, subsurface pH is generally unaffected by liming and often restricts soybean rooting depth.

In screening for drought tolerance among soybean plant introduction lines, scientists from the USDA discovered that line PI416937 had delayed wilting when grown on a sandy soil under nonirrigated conditions. The ability of PI416937 to maintain leaf turgor during drought was partially due to its tolerance for high soil aluminum. Genetic studies

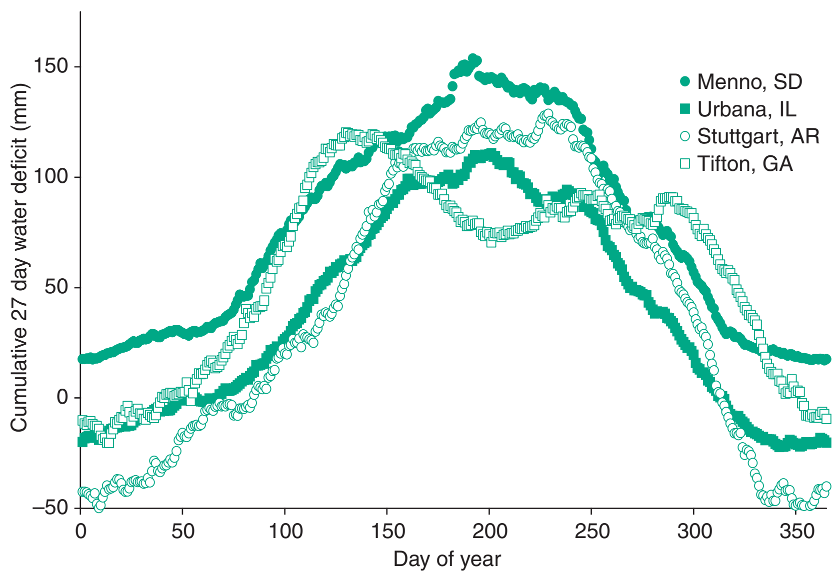

Figure 1 Cumulative 27 day water deficit for each day of year based upon long-term weather data at four sites in the US. Water deficit was calculated as the difference between precipitation and potential evapotranspiration using a centered 27 day running sum.

show that aluminum tolerance is a quantitative trait in soybean, and there are numerous genes associated with aluminum tolerance.

In addition to its greater tolerance to aluminum, PI416937 has a taproot that penetrates compacted soil layers more readily than does the taproot of the aluminum-sensitive cultivar “Weber.” The basal roots of Weber, however, penetrated compacted soil layer more easily than did those of PI416937. To realize the full benefit of deep rooting, it would be desirable to combine the ability of both tap and basal roots to penetrate compacted soil layers. In rice, regions of the genome have been identified that are associated with the ability of roots to penetrate an impervious soil layer. Given the genetic diversity in soybean for this trait, it might be possible to use genetic marker techniques to select plants with enhanced capacity for root penetration.

Increasing WUE

Open stomata on the leaf surfaces allow CO_2 to diffuse from the atmosphere to the sites of carboxylation in the chloroplasts. These same stomata allow the diffusion of water out of the leaf (transpiration). Thus, transpiration is inseparably linked with photosynthesis; the ratio of these two processes is a measure of water use efficiency. Because of the close coupling between water use via transpiration and carbon gain via photosynthesis, even small improvements in WUE could have large effects on the drought tolerance of soybean.

WUE can be roughly divided into a biological component and a meteorological component. The biological component regulates the stomatal conductance for gas exchange between the atmosphere and the leaf, and it determines the CO_2-diffusion gradient from the atmosphere to the chloroplast. Intuitively, if the photosynthetic efficiency of soybean is increased in the chloroplast, the CO_2 concentration in the chloroplast will decrease, resulting in a greater CO_2-concentration gradient from the atmosphere to the chloroplast and an increase in WUE. It should be noted that leaf photosynthesis would increase if stomatal conductance increases or remains constant with a decrease in the CO_2 concentration inside the leaf. It is precisely this mechanism that provides species having the C4 photosynthetic pathway (e.g., maize, sugarcane, and millet) greater WUE than species having the C3 photosynthetic pathway (such as soybean). If a decreased CO_2 concentration inside the leaf is associated with a substantial decrease in stomatal conductance, WUE will be increased but leaf photosynthesis may remain unchanged or could even decrease.

There are differences among soybean genotypes in this biological component of WUE. For example, the efficiency of the cultivar Young is ~25% greater than that of the aluminum-tolerant line PI416937 mentioned earlier. Crosses between parents differing in WUE have been used to identify molecular markers associated with this trait. A large-scale breeding program in Australia has led to the commercial release of drought-tolerant wheat with increased WUE. Although a comparable effort has not been undertaken in soybean to increase yield per unit of water used, the success of the wheat breeding program in Australia gives clear validity for this approach and encouragement that a similar improvement can be made in soybean.

The meteorological component of WUE is determined by the concentration gradient of water vapor from inside the leaf to the atmosphere. Water vapor concentration inside a leaf is saturated at any given temperature; this saturated water-vapor pressure increases exponentially as temperature increases. Therefore, WUE at the leaf level will be higher under relatively cool and humid growing conditions. Figure 2 illustrates the daily pattern of WUE for soybean leaves on plants grown at four locations. The values are calculated using long-term weather data and assuming the biological component was constant. This figure illustrates that WUE is approximately twice as great early in the growing season relative to the middle of summer. Thus, for locations where drought is common during the later portion of the growing season, early sowing of early maturing cultivars would not only avoid the drought but it also increases WUE due to the cooler temperatures early in the season.

Increasing Harvest Index

Drought during different stages of soybean development affects yield and yield components differently. As such, drought can increase, decrease, or not affect the harvest index, depending on when it occurs. Severe drought during vegetative stages that is relieved during reproductive stages may decrease the total amount of plant mass produced and also decrease the yield, but may have little impact on harvest index. Drought during flowering and early stages of pod formation that is relieved during pod filling will decrease the number of seeds produced, but the decrease in seed number is often compensated (at least partially) by an increase in the mass of individual seeds. Under these conditions, harvest index often increases. Plants exposed to drought during seed filling generally produce a large number of seeds, but the crop matures prematurely,

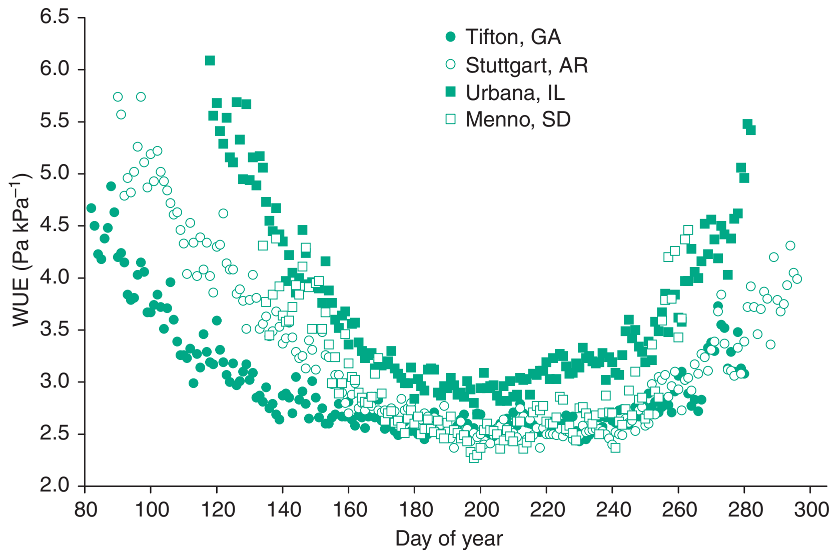

Figure 2 Average WUE vs. day of year during the growing season for Tifton – GA, Stuttgart – AR, Urbana – IL, and Menno – SD. (Adapted from Purcell *et al.* (2003) Drought avoidance assessment for summer annual crops using long-term weather data. *Agronomy Journal*, Nov/Dec issue.)

resulting in smaller seeds and a decrease in harvest index.

Equation [1] indicates that yield under drought conditions will be increased by maintaining a high HI. Practices such as minimum tillage, disruption of hard pans, decreasing evaporation from the soil surface by high population density and residue management, and increased soil–water infiltration are effective because they increase the amount of water available during seed growth and prevent the premature senescence associated with drought. In these cases, water conserved during vegetative development results in an increased water supply during seed filling, which results in increased harvest index.

Direct selection for high harvest index has generally not been used as a means to increase yield of rain-fed soybean. There are uncertainties in quantifying plant biomass at the end of the season. Considerable additional effort is required to determine harvest index for each breeding line – its values can be greatly affected by the stage of development at which drought occurs. Nevertheless, if variations exist among soybean lines for their capacity to remobilize vegetative dry matter into seed mass during drought, then selection for higher harvest index might be useful in identifying lines with improved drought tolerance.

Nitrogen Nutrition and Drought Response

To produce a grain yield of 4000 kg ha^{-1} requires ~260 kg of elemental N ha^{-1} for grain and approximately 40 additional kg N ha^{-1} for the rest of the plant. Depending upon the soil organic matter and previous cropping history, nitrogen fixation will supply from 40% to 90% of the crop's nitrogen requirement. As such, application of high rates of nitrogen fertilizer is rarely a viable economic option. Nevertheless, increasing the drought tolerance of nitrogen fixation to the same extent as inorganic nitrogen uptake and assimilation would be expected to increase yields. This response likely occurs because nitrogen fixation is more sensitive to drought than is photosynthesis and many other physiological processes. Studies conducted under dryland conditions, for example, show that soybean yield increased from 2373 kg ha^{-1} in the absence of nitrogen fertilizer to 2798 kg ha^{-1} when fertilized with 336 kg N ha^{-1}. Yield of the well-irrigated treatments did not respond to the additional nitrogen fertilizer. Other field experiments have shown that nitrogen accumulation decreases more than plant mass accumulation under drought stress, confirming the greater sensitivity of nitrogen fixation than photosynthesis to drought.

Fortunately, there is genetic variability in soybean for the sensitivity of nitrogen fixation to drought. "Jackson" was the first cultivar to exhibit prolonged nitrogen fixation during drought compared to several other cultivars of the time. Since then, eight additional plant introduction lines have shown the capacity for prolonged nitrogen fixation under drought conditions. These genetic lines could provide an important resource for crop improvement under drought conditions.

In summary, the linkage between photosynthesis and transpiration couples the amount of water available for transpiration to increasing yield under

drought conditions. This may include management and genetic options such as no-till production, high population density and early season vigor, deep tillage, aluminum tolerance, and deep rooting. Similarly, the efficiency with which water is used to produce plant mass and yield (i.e., WUE) could be increased where possible by confining the majority of the cropping period to the cooler portion of the season and by development of cultivars with high efficiency for water use. Increasing the amount of water available for transpiration during grain filling and using water more efficiently prevents the accelerated decline in senescence observed with late-season drought and maintains a high harvest index. Finally, genetic diversity in the tolerance of nitrogen fixation to water deficit offers an additional means to slow the senescence of leaves in response to late-season drought, and thereby increase soybean yield.

Managing Seed Composition

The two main commercial products of soybean seed are oil and protein. Accumulation of these components within the seed depends on key metabolic processes that are required for the successful production of the crop. Carbohydrates used for oil production are derived from photosynthesis; nitrogen, which is often the limiting nutrient for protein production, is derived from a combination of inorganic nitrogen sources and symbiotic nitrogen fixation. It is well known that genetic, climatic, and management variables contribute to the observed variability in seed composition and, therefore, the value of the crop for a specific end use. There is limited understanding, however, regarding the interactions between these environmental and genetic factors that determine the levels and quality of oils, proteins, and other seed constituents accumulated by the soybean seed.

Geographic Variation

The protein concentration of soybean seed produced in the US averages ~40.5%. There is wide variation, however, in seed protein across growing regions and between years within regions. Early studies on the geographic pattern of oil and protein levels of soybean seed in the United States showed that oil increased and protein decreased from the northern to the southern Midwest. Soybeans grown in northern and northwestern states typically have ~0.5% higher oil and 1.5–2.0% lower protein percentages than those grown in southern states. Protein content tends to be higher and oil lower in the southeast and Delta states compared to the Midwest. Results from many field studies suggest that temperature during seed filling accounts for much of the variation in seed composition, when other factors are fairly constant. Over large regions, however, factors such as water stress, tillage, soil acidity, soil nitrogen level, and previous crop history may be important determinants of final seed composition.

Breeding studies indicate that an increase in seed oil content and decrease in protein content has accompanied selection for high yield in short-season cultivars typically grown in the upper Midwest. These observations suggest that genetics, in addition to climate, contribute to the geographic variability in seed composition across the US, and may be an important factor determining the lower seed protein concentrations observed in northern growing areas. The differences in composition between geographic areas are large enough to affect pricing and marketing of the crop.

Accumulation of Seed Components

The developmental patterns of the major storage compounds in soybean seeds, protein, and oil are well documented. There is little accumulation of storage components during the initial phase of seed development, often termed the "lag phase," during which cotyledon cell numbers and the metabolic machinery for storage product synthesis increase. During the subsequent linear phase of seed growth, however, they accumulate rapidly in specific organelles called protein and lipid bodies. Cells of the cotyledons continue to accumulate storage compounds as long as their volume can increase. Once at maximum cell volume, the embryo begins to mature, metabolism of seed reserves slows, and the embryo prepares for desiccation.

Protein concentration ($g\,kg^{-1}$ dry weight) typically increases during the early cell division stage of seed development, and then remains fairly stable during the remainder of seed development. Final protein concentrations vary widely among soybean genotypes from 25% to over 50% of the final seed dry weight. Non-protein nitrogen comprises ~20% of the seed nitrogen during early seed development, and decreases rapidly as the seed develops to less than 5% at maturity. The oil concentration is low (3–5%) during early seed growth then increases rapidly to reach its maximum value when seed fill is 50–75% complete. Final oil concentrations vary from 14% to 25% among soybean genotypes.

The developing seeds obtain carbon from current photosynthesis, remobilized carbohydrates stored in vegetative plant parts, and carbon skeleton of nitrogen compounds delivered from the nodules or proteins hydrolyzed during leaf senescence. Likewise, the growing soybean seed can obtain nitrogen from

dinitrogen fixation, nitrogen uptake from the soil, and nitrogen remobilized from vegetative plant parts (i.e., leaves, stem, root, and pod wall). The ability of soybean to use nitrogen from either nitrogen uptake, dinitrogen fixation, or remobilized nitrogen from vegetative tissues gives the plant much flexibility to provide the seed with nitrogen. Seed protein can decrease when these three sources together cannot meet seed demand for nitrogen. Supplying supra-optimal levels of nitrogen in a hydroponics system has been shown to increase seed protein content, even in high protein lines. These increases, however, decreased grain yield. Apparently, the high seed protein trait (>40% of final DW) was not due to greater accumulation of nitrogen in the vegetative plant or greater nitrogen mobilization from vegetative tissues to the seed. Normal and high seed protein lines studied to date do not differ significantly in these attributes. Also, varying soil nitrate levels may alter the proportion of nitrogen in the seed derived from nitrogen fixation and remobilized nitrogen, but the source of nitrogen has no effect on the final nitrogen content or dry weight of the seed. *In vitro* studies using isolated embryos confirm that final seed composition is not simply a function of nitrogen supply to the plant or assimilate supply from the plant to the seed. Final seed protein concentration of high-protein genotypes is routinely greater than that of a normal-protein genotypes, regardless of the concentration of nitrogen supplied in the culture medium. Together, these results imply that the final composition of the seed is regulated to a large extent within the developing seed itself.

Temperature during Seed Filling

An important problem faced by soybean producers in the upper Midwest US is that the popular, high-yielding soybean varieties generally do not accumulate high levels of protein and oil in the seeds. Beans produced in Iowa, for example, contain ~35% protein and 18.5% oil, on average. This combination of protein and oil at the minimum processors can accept to make animal feeds. Wide variation in seed component levels across the region has made it very difficult for processors to meet industry standards for meal quality. As a consequence, soybean producers in the upper Midwest US often are paid less for the grain they deliver to the elevators. This situation will become even more problematic for soybean growers in the region as commodity markets shift to component-based pricing in the future.

Data from state and federal variety trials, and commodity reports often indicated a general correspondence between low seed protein content and low temperatures during seed filling. This correspondence suggests that the problem of poor seed composition in soybean might be a cold-stress response. Recent studies indicating genotypes that typically produce seed with 32–34% protein in the field have the genetic potential to accumulate up to 40% seed protein when grown at above-normal temperatures (35°C) during seed fill. Both rate and duration of dry weight, protein, and oil accumulation were affected by temperature. In general, rate of accumulation was a better predictor of final oil and protein concentration than was duration of filling. For the early maturing variety "Evans," the rate of oil accumulation (g/plant) was greatest when the day/night temperature was 20°C/12°C and decreased linearly with increasing temperature.

The effect of temperature on final seed protein and oil concentration is expressed within the seed itself. The plant supplies the seed with carbon in the form of sugars such as sucrose and amino acids such as glutamine. Because there are no direct vascular connections between the seed and the maternal plant, the embryo is in essence bathed in a solution of nutrients supplied by the plant. Using an *in vitro* system, which mimics this bathing solution, it has been determined that capacity of the developing embryo to take in sucrose and glutamine from this solution does not limit the accumulation of protein at low temperature. As temperature increases, the rate of sucrose and glutamine uptake also increases. But the ratio of sucrose to glutamine uptake remains at about the same maximum value (~2.2 mol sucrose/mol glutamine) regardless of the growth temperature. These results indicated that soybean possesses adequate capacity for sugar and amino acid uptake at low temperature, and that the ratio of uptake of protein and oil precursors did not dictate the final composition of the seeds.

Most of the carbon deposited into protein is derived from sucrose. A significant amount of carbon from amino acids is metabolized into oil. Thus, carbon from glycolysis is available for protein synthesis, and carbon skeletons from amino acids are available for oil synthesis presumably via the Krebs cycle. *In vitro* studies have shown that the temperature during seed filling has a direct impact on the uptake and metabolism of protein and oil precursors supplied from the plant. At low temperature most of the glycolytic carbon is diverted into oil. At higher temperatures, most of the carbon is diverted into protein. Apparently, the response of oil accumulation to temperature during early reproductive growth reflected a shift in metabolic capacity for oil synthesis, and was not simply a direct effect on the rate of oil biosynthesis. This increase in protein synthesis with temperature may reflect a temperature-dependent

competition between protein and oil metabolism. In effect, temperature controls the flow of carbon at metabolic "crossroads" leading to protein or oil synthesis. A combination of gene expression profiling, protein profiling, and metabolic flux analyses is being employed to identify these key metabolic crossroads and to design ways to modify the carbon flow through them to direct the formation of protein and oil to meet end-user needs.

Water Supply

Seed protein concentration increases have been observed in water deficit conditions and soils with root limiting factors such as low subsoil pH or fragipans. The response of seed oil and protein concentration to water deficit, however, varies with the time and duration the water deficit occurs. Early seed-fill water deficit with favorable conditions during the remainder of the season decreases seed protein while increasing oil. High mean temperatures above 25°C, often associated with water deficit, typically increase the final protein concentration in the seed. Water deficit late in seed fill increases protein and decreases oil concentrations. An index method between irrigated and non-irrigated treatments has been used to show that oil content was more sensitive to water stress than protein content. The varied response of seed protein and oil to the timing of water deficit probably explains why, in the literature, there are poor correlations between rainfall and final seed protein and oil concentration.

Management Factors

Seed protein concentration for a given genotype may vary by 8% or more across environments. In addition to the response to climatic conditions, management factors such as soil inoculation, planting date and pattern, and soil fertility also can influence seed composition. Symbiotically fixed nitrogen and inorganic nitrogen are required for maximum yield and high protein seed. A host of soil factors has been reported to affect *Bradyrhizobium japonicum* and nitrogen fixation: soil pH, soil organic matter content, initial soil nitrate level, soil temperature, and soil moisture supply. High soil nitrogen from either mineralization of organic matter or addition of inorganic fertilizers decreases nodule weight, nodule number, weight per nodule, and rate of nitrogen fixation. Poor nodulation reduces plant and seed nitrogen concentrations and yield. Using "superior rhizobium strains" can improve yield by increasing vegetative growth and pod number. The benefit to yield formation, however, is realized prior to seed fill. Dinitrogen fixation rates during seed fill reportedly are similar between the superior and indigenous strains, suggesting that dinitrogen fixation during seed fill was limited by factors other than rhizobia strain. While inoculating seed with rhizobia does not always increase grain yield, stimulating indigenous rhizobia to initiate nodule formation in cool soils has proven to be an effective means to increase yield and seed protein content. By inoculating seeds with rhizobia incubated with the soybean isoflavone, genestein, researchers in Canada increased nodule formation, total seasonal nitrogen fixation, and seed protein content on field-grown plants. These results clearly indicate the benefits of establishing nitrogen-fixing activity earlier in the season, but a cost-effective method for doing so is not currently available.

Late planting dates shift the period of seed fill later into the fall when temperatures may be lower and day length shorter. Lower temperatures during early seed development can decrease seed value as total protein plus oil decrease with temperature. Delayed planting reportedly increases seed protein and linolenic acid levels while decreasing the oil and oleic acid levels. Recent reports suggest that the low linolenic acid trait might be amplified by planting these cultivars early (April) in the warmer temperatures of the Southeast. Early planting dates would place flowering and early seed development during warmer periods when the probability of high temperature and water deficit is high.

Soybean seedlings depend on soil nitrogen during the first few weeks of development before nodules develop and dinitrogen fixation commences. As such, "starter" fertilizers can improve early seedling establishment and increase plant growth, which can increase yield if canopy development is otherwise limited. In northern growing areas, responses to starter fertilizer often have been associated with restricted root growth or cool soil temperatures. In southern states, response to starter fertilizer has been evaluated for late July planting of soybean in double-crop systems, which are prone to water deficits. A starter fertilizer of $50\,\mathrm{kg\,ha^{-1}}$ on soybean planted late in July, for example, decreased dinitrogen fixation but increased plant dry weight and nitrogen concentration. A yield increase from this starter fertilizer was associated with an increase in seed number per unit area, probably as a result of greater light interception and higher rates of canopy photosynthesis. Yield increases associated with larger seed size have been observed for environments receiving irrigation during seed fill. In one study, a determinate cultivar responded to starter fertilizer by increasing seed nitrogen concentration, while an indeterminate isoline responded with an increase in seed number and yield.

There has been considerable interest in postflowering application of nitrogen fertilizer, especially for late plantings on sandy soils where nodulation is poor due to high soil temperatures or water deficit. The addition of nitrogen fertilizer at flowering or beginning seed has been shown to increase seed yield and seed protein concentration in some cases. Yield decreases, however, also have been observed with postflowering foliar application of nitrogen. Soybean responses to nitrogen fertilizer have been inconsistent probably because of the many interacting climatic and soil factors involved. The changes in seed nitrogen concentration are likely related to the interaction of seed protein with temperature (high or low), water supply, and initial soil nitrogen levels.

In summary, increasing soil nitrogen availability and/or nitrogen fixation rates can lead to an increase in seed yield as a result of increased plant growth. Changes in seed number and yield appear to dominate soybean response to supplement nitrogen with only small changes in seed composition. A soybean crop grown on soils high in organic matter or residual nitrogen have the potential to produce seeds with increased protein concentration in response to late-season nitrogen uptake as the capacity for dinitrogen fixations decreases.

Iowa State University, Ames, IA, USA

Introduction

Soybeans vary widely in their appearance and composition. The main constituents of soybeans, in descending order, are protein, oil, complex carbohydrates, oligosaccharides, simple sugars, and minerals. Phytochemicals in soybeans have gained prominence since the 1990s especially isoflavones, saponins, and phenolic acids because of their potential health-protective effects. Soy isoflavones in particular have been associated with a variety of other improved physiological states, including reduced cholesterol levels, anticarcinogenicity, and improved bone health.

Most legumes contain 20–25% protein, but soybeans typically contain 30–45% protein (moisture-free basis), and average ~35% at 13% moisture. Protein-content levels as high as 55% (moisture-free basis) have been observed. The oil content typically ranges from 15% to 24% and averages about 20% on a 13% moisture basis. The composition varies with growing area, for example soybeans from northern and mid-western areas of the United States typically contain 1.5–2% less protein and 0.2% more oil than beans grown in southern states. One Iowa soybean processor has begun offering premiums for soybeans containing higher than normal oil contents.

The total crude fiber content of soybeans is ~4.4% at 13% moisture. These materials are predominantly

cellulose, hemicellulose, and pectin. The outer hull, typically 8% by weight of the bean, is especially rich in crude fiber (35%). Fiber is hard to digest and contributes little to the nutrition of swine and poultry, the primary markets for soybean meal.

The total sugar content of soybeans is 4.9–9.5% at 13% moisture. Of the total sugar content, ~60% is sucrose, 10% raffinose, and 30% stachyose. Raffinose and stachyose are oligosaccharides and cause flatulence (intestinal gas) in humans and reduced feed-efficiency in livestock. One seed company has recently developed a soybean line that is low in oligosaccharide content and high in sucrose content.

Isoflavone content of soybeans varies from 800–4000 $\mu g\,g^{-1}$ on aglycon basis. Soybeans contains 12 isoflavones, namely genistein, daidzein and glycitein, as β-glucosides, 6″-O-malonylglucosides, 6″-O-acetylglucosides, and aglycons. Soy saponin concentrations vary in a similar manner to isoflavones ranging from 2–12 $\mu mol\,g^{-1}$. Because of the variety of glucoside forms of saponins and isoflavones, their concentrations should be expressed in μmol. The isoflavones and saponins fractionate with the seed protein and are not lipid-soluble. As soybeans are fractionated into food ingredients, the forms of the isoflavones and saponins are rearranged depending on the extent of heat processing and the method of protein fractionation.

Generally, soybean meal is sold on a 44% protein basis and 48% when soybeans are de-hulled (Hi-Pro meal). The average price of soybeans during the 1997–98 crop year was $6.47 per bushel. Oil sells for ~2 times the value of meal. Typical selling prices for soybean oil were 25.7 cents per pound and for meal (44% protein) were $197 per ton (t) or 9.9 cents per pound during 1998. In 2002, crop year prices were considerably lower.

Recent developments in breeding and genetic modification of soybeans have achieved: new fatty acid compositions, e.g., <2% linolenic acid and >80% oleic acid to improve oxidative stability; removal of all lipoxygenase isozymes to improve the flavor of soy protein ingredients; elimination of oligosaccharides to eliminate intestinal gas; altered protein and amino acid composition to improve functional and nutritional properties; and inserted vaccines for human and animal health. While genetic engineering holds great promise for the future (healthier foods, reduced environmental impacts, increased yield, lower input costs, etc.), consumers have begun to question the safety of this new technology.

Proteins

Glycinin and β-conglycinin comprise 65–80% of the protein fraction or 25–35% of the seed weight. Glycinin is classified as a legumin, which is characterized by molecular weights of 300–400 kDa and sedimentation coefficients of 11S ± 1S. β-Conglycinin is a vicilin, which is in the range 150–250 kDa, glycosylated and has sedimentation coefficients of 7S ± 0.5S. In soybeans, the major proteins, glycinin and β-conglycinin, are frequently described by their respective sedimentation values, 11S and 7S, but such fractions often are impure. The 7S fraction of soy protein contains, in addition to β-conglycinin, lectins, lipoxygenase, and β-amylase.

β-Conglycinin is a trimer and/or hexamer in solution and probably occurs in both forms in the seed. Two similar peptides, α and α' (57 kDa), and a glycosylated β-peptide (42 kDa) are assembled in the mature protein in a nonrandom set of seven forms, $\alpha'\beta_2$, $\alpha\beta_2$, $\alpha\,\alpha'\beta$, $\alpha_2\beta$, $\alpha_2\,\alpha'$, α_3, and β_3 with molecular weights of 125–171 kDa. The α and α' subunits have 1–2 mol cysteine/mole peptide while the β-peptide has no cysteine. The health benefits of consuming soy protein are attributed primarily to β-conglycinin.

Glycinin is a hexamer, although older literature calls it a dodecamer. It is composed of six nonrandomly paired acidic and basic peptides. The acidic peptides have molecular weights of 44, 37, and 10 kDa; the basic peptides are 20 kDa. The acidic–basic (AB) pairs have been identified in the experimental line, CX635-1-1-1, and are shown in Table 1. Seven acidic and eight basic peptides have been identified in 18 cultivars. There appear to be sulfur-rich and -poor AB pairs.

Soybeans contain two main classes of protease inhibitors or trypsin inhibitors (TI), although there appear to be many isogenic variants. The principal two classes are the Kunitz inhibitor with MW of 21 500 and the Bowman-Birk inhibitor with MW of 8000. The Kunitz inhibitor acts only on trypsin while the Bowman-Birk protein inhibits both trypsin and chymotrypsin. Moist heat treatment denatures ~90% of the TI activity with the residual being heat stable. TI affects animals of guinea-pig-size and smaller but has little effect on larger animals,

Table 1 Glycinin acidic–basic complexes from CX635-1-1-1

AB-complex	*S-amino acids*	*Molecular weight* (kDa)
$A_{1a}B_2$	14	57
$A_{1b}B_{1b}$	12	57
A_2B_{1a}	14	57
A_3B_4	9	62
$A_5A_4B_3$	3	67

Data from Nielsen (1985) Structure of soy proteins. In: Altschul AM and Wilcke HL (eds.) *New Protein Foods, vol. 5. Seed Storage Proteins*, pp. 27–64. New York: Academic Press.

except for weanling pigs. Recently, Bowman-Birk TI has been demonstrated to be an anticarcinogen and is currently in Phase II cancer trials. There are reports that TIs exert a carcinogenic effect on rodents. There has been interest in recovering and purifying soybean protease inhibitors to treat AIDS patients.

The Food and Drug Administration of the United States has approved a health claim for soy protein that as part of a heart healthy diet 25 g per day of soy protein will contribute to improved cardiovascular health.

Lipids

Soybean lipids contain ~2–5% phospholipids, depending on the growing conditions, and 1.6% unsaponifiables. The balance is chiefly triacylglycerols.

Oleic (18:1), linoleic (18:2), palmitic (16:0), stearic (18:0), and linolenic (18:3) acids are present in soybean oil along with traces (less than 1%) of myristic (14:0), palmitoleic (16:1), heptadecanoic (17:0), eicosenoic (20:1), arachidic (20:0), behenic (22:0), and erucic (22:1) acids. The range of the acyl groups present in soybean oil has been extended by mutation breeding and selection to the values reported in Table 2.

The acyl groups are distributed asymmetrically in the triacylglycerols with all the saturates on the *sn*-1 and -3 positions and linoleate concentrated on the *sn*-2 position. Generally, the *sn*-1 contains more palmitate and stearate than *sn*-3, and the oleate is enriched on *sn*-3. Phospholipids contain the same acyl groups found in the triacylglycerols, but the concentration of palmitate is generally higher and oleate lower. Phosphatidyl choline (50%), ethanolamine (26%), and inositol (18%) are the chief phospholipid components along with lower concentrations of phosphatidic acid and phosphatidyl serine.

The unsaponifiables contain sterols, hydrocarbons, and tocopherols. The chief sterols (3.5 mg g^{-1} oil) are β-sitosterol, campesterol, and stigmasterol. The tocopherols (~1.25 mg g^{-1} oil) are typically more than 70% gamma with smaller amounts of delta, and alpha.

Table 2 The range of acyl group percentages produced in soybean lipids by mutation breeding and genetic engineering, and the composition of a typical unselected variety

	Range	*Typical value*
Palmitate	3.5–30	10
Stearate	2.5–32	4
Oleate	8.0–85	26
Linoleate	2.0–60	52
Linolenate	1.8–13	8

Methods to Measure Composition

Proximate analyses for moisture, protein, crude free fat, crude fiber, ash, and total carbohydrate have been adopted by the American Oil Chemists' Society, the American Association of Cereal Chemists, and the Association of Analytical Chemists. All composition values for soybeans are reported either on a moisture-free basis or at 13% moisture.

Several methods are acceptable for moisture determination, but the most widely used procedure involves measuring the weight loss when drying the ground sample for 3 h at 130°C.

Protein is estimated from Kjeldahl nitrogen. The nitrogen content is multiplied by a factor of 6.25 to convert to protein values despite the major soy protein, glycinin containing only 17.5% nitrogen (equivalent to a N conversion factor of 5.7).

Oil content is determined as crude fat by continuously extracting dried ground samples with petroleum ether for 5 h. Total fat, which includes bound fat as well as free fat, requires acid hydrolysis of the sample prior to extraction. In recent years, the use of near-infrared reflectance (NIR) and transmittance (NIT) has become widespread for rapid estimation of grain composition, especially moisture, protein, and oil. These spectrophotometers must be calibrated against the standard wet chemical methods described above. Moisture is also routinely measured by electrical capacitance.

Crude fiber is measured as the weight loss on incineration of the oven-dried residue remaining after digestion of the sample with boiling dilute sulfuric acid followed by boiling dilute sodium hydroxide.

Ash is primarily composed of noncombustible minerals and is determined by heating the ground sample in a muffle furnace for 2 h at 600°C. Soybeans contain ~4.7% ash at 13% moisture.Total carbohydrate is often estimated as the difference after subtracting other constituents. This method does not discriminate between oligosaccharides and other sugars, and it often gives inflated values. Sugars can be extracted with hot aqueous ethanol and quantified by gas or liquid chromatography.

Acyl group composition of soybean lipids is generally determined by gas chromatography. Lipid classes are separated by thin-layer or liquid chromatograms.

Qualitative and quantitative analyses of the individual proteins have been performed by immunoelectrophoresis and/or SDS polyacrylamide electrophoresis.

Isoflavones are assayed by reverse-phase (RP) HPLC of 80% acetonitrile extracts and absorbance detection at 250–260 nm. Methanol and ethanol tend to underextract some isoflavone forms. Saponin analysis is typically by RP-HPLC with absorbance detection at 290 and 205 nm, depending on form, although older methods used silica-based TLC. The major impediment to accuracy has been the lack of suitable standards, although most of the isoflavone forms are now available.

Grading Standards

The Federal Grain Inspection Service (FGIS) for the United States has established grading standards for soybeans (Table 3) to facilitate marketing and trade. Much more detail than can be provided here is available at the FGIS website http://www.usda.gov/gipsa/reference-library/brochures/soyinspection.pdf. Soybeans are divided into two classes based on color: yellow soybeans and mixed soybeans. Each class is divided into four numerical grades (US No. 1, 2, 3, and 4) and a US Sample Grade those soybeans, which do not meet the requirements of any of the numerical grades. Special grades (e.g., garlicky and infested) are provided to emphasize special qualities affecting the value, and are added to and made part of the grade designation. Six factors are considered in assessing grade designation: test weight, heat damage, total damage, foreign material, splits, and soybeans of other colors. Although moisture, protein, and oil contents are not part of the official grading standards and do not affect numerical grade, they may be specified on contracts in some markets. NIT is used for rapid estimation of moisture, protein, and oil contents.

Test weight, which is the weight in pounds of grain per Winchester bushel (35.2 l), is determined on a 1¼ quart (1.18 l) sample before removing foreign material using an official test weight apparatus. If the test weight is extremely low, the soybeans may contain less oil. All other factors are measured as percentages of total sample weight. Foreign material is determined by sieving and is all matter, including soybeans and soybean pieces that readily pass through an 8/64-inch (3.2 mm) round-hole sieve and all matter other than soybeans remaining on the sieve after sieving. Foreign matter (other grains, weed seeds, pods, leaves, stems, etc.) reduces oil and protein contents and storage life. Splits are soybeans with more than one-fourth of the bean removed and which are not damaged, and are determined by sieving a portion of the grain after removing foreign material. Splits, which result from mechanical damage during handling and overdrying, reduce storage life and oil yield, and increase losses during oil refining. Damaged kernels are soybeans and soybean pieces, which are badly damaged by the ground, weather, frost, heat, insects (stinkbug-stung kernels only are counted at one-fourth the actual percentage), mold, or sprouting, and are determined by hand-picking after removing foreign material. Damaged kernels reduce storage life and oil yield, adversely affect oil color, and increase refining loss. Soybeans of other colors are those, which have green, black, brown, or multiple colors. These soybeans may affect oil color by contributing undesirable pigments.

During the 2002 crop year, almost 27 million metric ton (Mt) of soybeans were exported from the United States. Of that amount, 4.8% was US No. 1, 94.6% was US No.2, 0.4% was US No. 3, and 0.1% was US No. 4. By comparison with Brazilian soybeans, US soybeans are typically slightly lower in oil content (6 year average of 1.2% lower oil content) but are lower in foreign matter, damage, free fatty acid (free fatty acid increase oil-refining loss) and moisture contents, and are higher in test weight.

Grading standards are similar between countries of origin, but differ in some details. For instance, Brazil and Argentina have an export grade for soybeans, Grade No. 1, which limits foreign matter to 1%. Brazilian grades specify a maximum of 14% moisture but Argentina, a maximum of 13%. The moisture content normally regarded as safe for long-term storage is 13%. The Mexican system does not consider test weight as a grading factor but does consider oil acid value (a measure of free fatty acid content). Entirely different criteria are used for grading food-grade soybeans destined for soymilk and tofu.

Table 3 Official grades and grade requirements of the Federal Grain Inspection Service, United States Department of Agriculture

US sample grade	*Minimum test weight per bu. (lbs)*	*Damaged kernels*		*Maximum limits*		
		Heat damaged (%)	*Total (%)*	*Foreign material (%)*	*Splits (%)*	*Soybeans of other colors (%)*
US No. 1	56.0	0.2	2.0	1.0	10.0	1.0
US No. 2	54.0	0.5	3.0	2.0	20.0	2.0
US No. 3	52.0	1.0	5.0	3.0	30.0	5.0
US No. 4	49.0	3.0	8.0	5.0	40.0	10.0

Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 5391, Elsevier Ltd.

Typically, individual purchasers establish their own criteria often including seed size, seedcoat color, number of hard beans (germination or soaking test), total sugar, oil peroxide value or thiobarbituric acid test (measures of oil oxidation), acid value, protein dispersibility or solubility. Organic production or genetically modified free soybeans may also be criteria for food-grade soybeans.

Processing

T Wang, Iowa State University, Ames, IA, USA

Soybean is the dominant oilseed produced in the world due to its favorable agronomic characteristics, its high-quality protein, and its valuable edible oil. It comprises over a half of all oilseeds produced worldwide (Figure 1). The United States ranks number one in soybean production (8.24 million ton (Mt)), followed by Brazil, Argentina, China, and EU-15 (4.28, 3.28, 3.26, and 2.87 Mt, respectively). The production of soybeans and soybean oil is driven by the needs for soy protein meals that are extensively used in commercial feeds for poultry, swine, and cattle. Soybean oil accounted for 80–90% of total edible oil consumption in the United States in 1998 because of its availability and its many desirable characteristics, including compositional and functional properties.

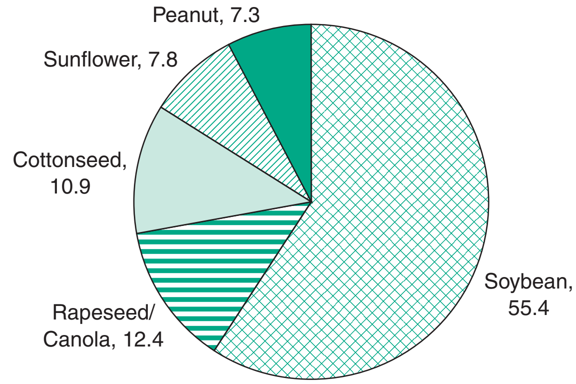

Figure 1 Percentages of five major oilseeds produced in the world during 2000–01.

This article describes the composition of soybean seed and oil, extraction, refining, and further processing of the oil, and processing and utilization of by-products from oil refining. Oil oxidation and its measurement are also discussed briefly due to the impact of this chemical degradation on oil quality. This article concludes with a general description of the uses of soybean oil as cooking and salad oil, in margarine, shortening, mayonnaise, and salad dressing.

Composition

Seed Composition

Mature soybeans are oval shaped and their sizes are variety dependent. The seed consists of three major parts: seedcoat or hull, cotyledon, and germ or hypocotyls as shown in Figure 2. Soybean oil is contained in the lipid bodies in the cotyledon cells. The composition of these structure components is shown in Table 1.

Oil Composition

Oil recovered by solvent extraction or mechanical pressing is termed crude soybean oil and it contains various classes of lipids, including neutral lipids (tri-, di-, and mono-acylglycerols), free fatty acids (FFAs), and polar lipids such as phospholipids (PLs). It also contains a minor amount of unsaponifiable matter that includes phytosterols, tocopherols, and hydrocarbons such as squalene. Trace metals are found in soybean oil in ppm concentration. When the oil is refined, concentrations of all minor constituents are reduced. The typical composition of crude and refined soybean oil is shown in Table 2.

Sphingolipids is an area of research with increasing activity in recent years. Soybeans are a relatively rich source of sphingolipids, a class of polar lipids which are ubiquitous constituents of the cell membrane and are highly bioactive. The hydrolyzed products of sphingolipids are used by cells to regulate growth, differentiation, and apoptosis. There is evidence that these lipids inhibit colon carcinogenesis in experimental animals at a human diet-equivalent concentration. They may reduce colon cancer risk in humans and inhibit skin cancer development. Little is known about how sphingolipid content varies with soybean variety and processing.

Fatty Acid Composition

Typical fatty acid composition of commodity soybean oil, in comparison with the other major vegetable oils, is shown in Table 3. Soybean oil has relatively high content of linoleic and linolenic acids. These are both essential fatty acids for humans and therefore of dietary importance but they are also the reason for the oxidative instability of this oil. Processing techniques such as hydrogenation and lipid composition modification through traditional plant breeding or

genetic transformation have been used to modify the fatty acid composition to improve its oxidative or functional properties.

Oil Extraction

The two common processes for soybean oil extraction are solvent extraction and mechanical pressing, but in the United States less than 1% of the soybeans is processed by mechanical means. Solvent extraction with hexane is the standard practice in today's modern processing facilities. There are three major steps in solvent extraction: seed preparation, oil extraction, and desolventizing of the oil and meal. Conventional seed preparation includes drying, cleaning, cracking, optional de-hulling or decortication, conditioning, and flaking of the seeds. The option of expanding after flaking is used to improve oil extraction, percolation, and solvent drainage, and is accompanied by a doubling of the throughput. The Alcon process is a flake-heating treatment aimed to improve the degumming efficiency of the crude oil. A very low level of PL in degummed oil can be achieved and therefore the oil can be physically refined.

Hexane extraction of soybeans is a diffusion process achieved by immersing solid in solvent or percolating solvent through a bed of solids. Rotary (deep-bed), horizontal belt, and continuous loop extractors are used for soybeans. Solvent, recovered from the miscella (mixture of solvent and extracted oil) by double-effect evaporator and steam stripping and from flake by a desolventizer toaster, is recovered and recycled.

Table 2 Typical composition of crude and refined soybean oil

Component	*Crude oil*	*Refined oil*
Triacylglycerols (%)	95–97	>99

Refining of Soybean Oil

The minor components of soybean oils include PLs, FFAs, chlorophyll pigment, oxidation products, and other unsaponifiable components (tocopherols, sterols, hydrocarbons, etc.). Some of these minor components negatively affect oil quality while others may play a positive role in nutrition and function. The goal of refining is therefore to remove the undesirable components and, at the same time, to maximize retention of the beneficial ones. An overview flowchart of soybean oil refining is presented in Figure 3.

"Degumming" is a process of removing PLs (gums) from crude soybean oil to improve its physical stability and to facilitate further refining. The water degumming procedure is simple, but its efficacy is influenced by the quality of crude oil. PLs can exist in hydratable form that can be readily removed after hydration, or in nonhydratable form that cannot be removed by this procedure. The nonhydratable phospholipids (NHPs) are probably calcium and

Table 3 Average fatty acid composition (wt.%) of oils from soybean and other oilseeds

Fatty acid		*Soybean*	*Canola*	*Cottonseed*	*Sunflower*	*Peanut*

Lignoceric	24:0		0.2			1.0

magnesium salts of phosphatidic acids resulting from enzymatic hydrolysis of the PLs. This degradation results from seed damage during storage and handling or from improper seed preparation. Normal quality soybean oil from conventional solvent extraction has ~90% hydratable PLs and 10% NHPs. Phosphoric acid or citric acid can be used as an aid for more complete removal of NHPs, but their presence in the gum will reduce its quality due to darkening of the gum. Total PLs in crude soybean oils range from 1.1% to 3.2%.

Degumming can be achieved in batch or continuous fashion. In batch degumming, soft water at the same percentage as total PLs is added to heated (70°C) oil and mixed thoroughly for 30–60 min, followed by settling or centrifuging. In continuous water degumming, heated oil is mixed with water by an in-line proportioning and mixing system and the mixture is held in a retention vessel for 15–30 min before centrifugation. A well-degummed soybean should contain less than 50 ppm of phosphorus, well below the 200 ppm level specified in the National Oilseed Processors Association trading rules for crude degummed soybean oil. Degumming prior to physical refining of soybean oil requires a more complete removal of the phospholipids to prevent darkening during fatty acid distillation.

"Neutralization" is a process of removing FFA, an oil decomposition product, from the oil. The process is also described as de-acidification or caustic

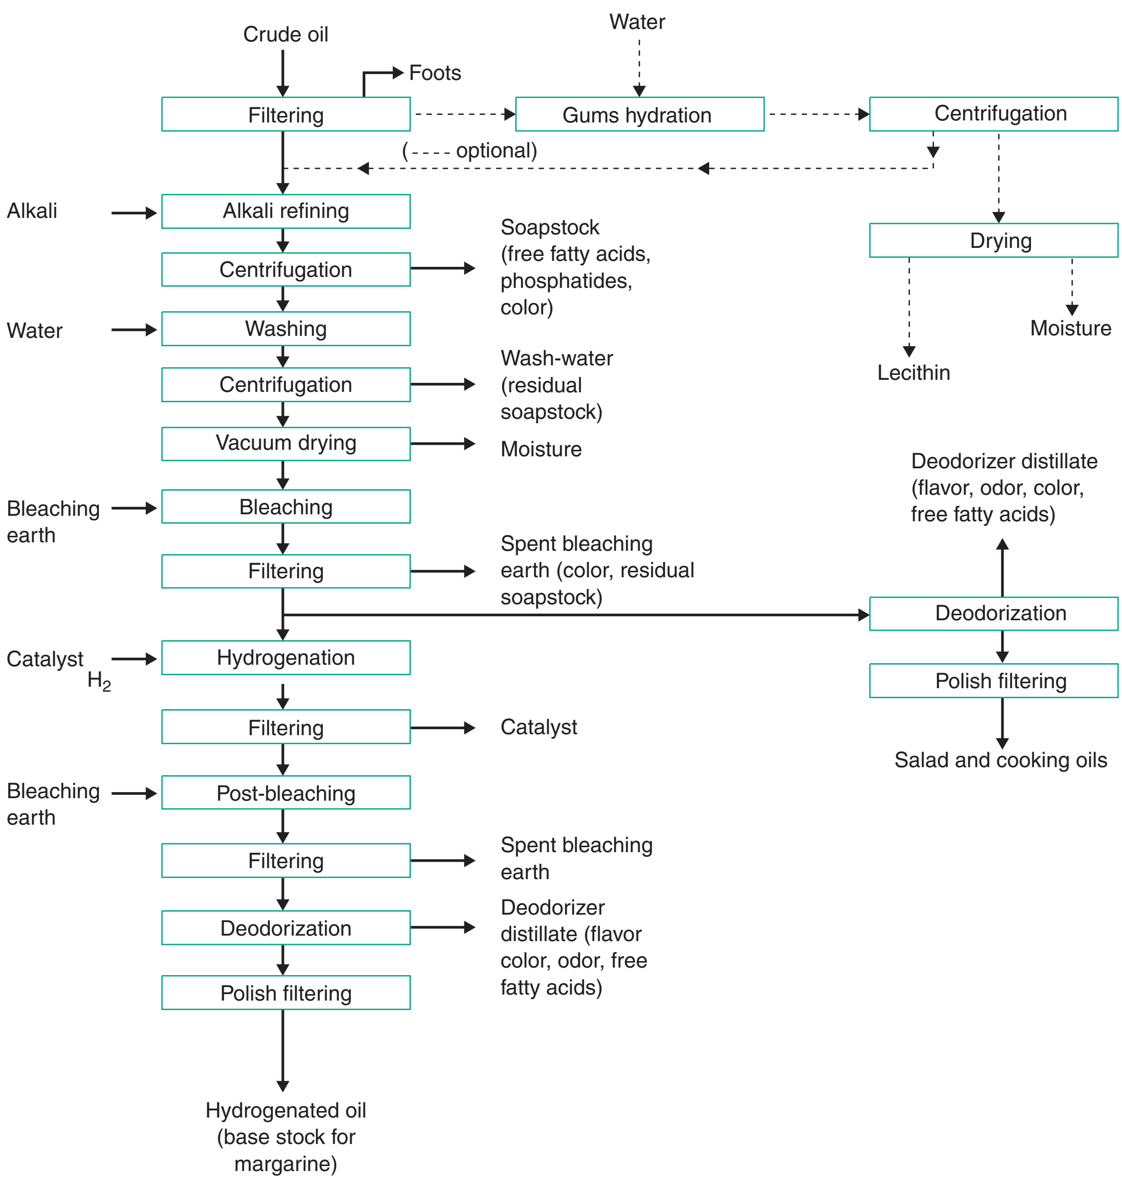

Figure 3 Diagram of soybean oil refining. (Courtesy of Center for Crops Utilization Research, Iowa State University.)

refining. It is achieved by treating the soybean oil with aqueous alkaline solution (generally sodium hydroxide) to neutralize the FFA in a batch or continuous system. The soap formed in the reaction also adsorbs natural pigments, the unhydrated gum, and mucilaginous substances contained in the oil. Settling or centrifugation is used to remove the soap. More details on soybean oil neutralization are discussed by Erickson.

"Bleaching" is a process designed not only to remove the pigment (chlorophyll) but, more importantly, to break down peroxides (primary oxidation products) into lower-molecular-weight carbonyl compounds that can be subsequently removed by deodorization. In soybean oil refining, color reduction occurs at each step of degumming, neutralization, bleaching, hydrogenation, and deodorization. Nevertheless, the most significant reduction of chlorophyll is during bleaching. Acid-activated bleaching clay is most effective in adsorbing chlorophyll and decomposing peroxides. Low levels of phosphorus (5–10 ppm P) and soap (10–30 ppm) in the neutralized oil are required to maximize the bleaching effect. The desired bleaching endpoint is zero peroxide, so the amount of bleaching earth should be adjusted to the quality of oil to be bleached. Earth dosage ranges from 0.3% to 0.6% for typical soybean oil. Successful bleaching can be achieved by atmospheric batch bleaching, vacuum batch bleaching, or continuous vacuum bleaching at temperatures between 100°C and 120°C for 20–30 min. More details of soybean oil bleaching are described by Erickson.

"Deodorization" is usually the last step in oil refining and it is a steam stripping process in which good-quality steam (1–3% of oil), generated from de-aerated and properly treated feed water, is injected into soybean oil under high temperature (252–266°C) and high vacuum (< 6 mm Hg). Under these conditions peroxides are decomposed, and the FFA and odorous compounds are vaporized. Heat bleaching is achieved by maintaining the oil for 15–60 min at high temperature to ensure considerable decomposition of carotenoid pigments. During the deodorization process, many desirable reactions take place but some undesirable ones such as lipid hydrolysis, polymerization, and isomerization also occur. Therefore, deodorization temperature must be carefully controlled to achieve optimum quality finished soybean oil.

There are three types of deodorization operations. The batch process is the least common, due to its low efficiency and inconsistent product quality. Semicontinuous and continuous deodorizers have improved processing efficiency. There are several configurations of the continuous deodorizer, including single-shell cylindrical vessel type, vertically stacked tray type, and the thin-film packed column type. This last one provides excellent fatty acid stripping with minimum use of steam, but it achieves neither desired heat bleaching nor effective deodorization due to the relatively short retention time. Therefore, a retention vessel has to be used after deodorization by column distillation.

Changes in oil quality during refining of soybean oil are shown in Table 4.

Comparing oxidative stability of soybean oil at different stages of refining, crude oil is the most stable while highly purified oil is the least stable. Changes in composition of minor components during refining are shown in Table 5.

Hydrogenation

The high degree of unsaturation, particularly the significant level of linolenic acid of soybean oil, limits its food application due to its low oxidative stability. Partial hydrogenation is used to increase the melting temperature and, at the same time, to improve the oxidative stability of soybean oil.

When oil is treated with hydrogen gas in the presence of a catalyst (nickel) under appropriate agitation and temperature conditions, it becomes a semisolid or plastic fat suitable for many food applications. Selectivity is often used to describe the relative reaction rates of the fatty acids from the more unsaturated to the more saturated forms. Generally, selectivity increases with increase in temperature and in catalyst

Table 4 Effect of processing steps on quality of soybean oil

	Phosphorus (ppm)	*Iron (ppm)*	*Chlorophylls (ppm)*	*Peroxide value (meq/kg)*	*Tocopherol (ppm)*	*Free fatty acid (%)*

concentration and with decrease in hydrogen pressure and in agitation rate.

During hydrogenation various side reactions occur, and some of which have a strong impact on the physical and nutritional properties of the products. Double bond isomerization or *trans* fatty acid formation is the most important side reaction. The *trans* double bond is a thermodynamically more stable configuration than its *cis* counterpart and it is produced in significant quantity during partial hydrogenation. The *trans* fatty acids have a much higher melting point than their *cis* isomers; therefore, fat products with considerable *trans* fatty acids will have elevated melting points, which is desirable in shortening and margarine applications. However, the recently established link between *trans* fat consumption and health consequences has prompted research to reduce its use in foods.

Inter-Esterification

Inter-esterification is a term used to describe reactions in which fatty acid esters react with FFAs (acidolysis), alcohols (alcoholysis), or with other fatty acid esters (*trans*-esterification). In food application, inter-esterification often refers to the reaction between different oils or fats with their fatty acyl groups rearranging among the molecules.

Inter-esterification is conveniently achieved by an alkali methylate-catalyzed reaction under mild temperature (20–100°C). Microbial lipases are also widely used as biocatalysts in enzymatic inter-esterification. In contrast to the chemical process, the enzymatic process can be more selective if an enzyme with positional specificity is used, and it is usually much slower and more sensitive to the reaction conditions. The new developments in lipase-catalyzed inter-esterification have resulted in industrial applications of this process. Most inter-esterification reactions are still achieved with a chemical catalyst. Randomization is a special form of inter-esterification in which acyl groups of a single oil or fat rearrange, resulting ultimately in a change of the natural distribution to a completely random pattern.

Recent reports linking consumption of *trans* fatty acids to the risk of coronary heart disease have generated much interest in producing margarines and shortenings that do not contain *trans* fatty acids. To achieve this, liquid oil and completely hydrogenated hard stock are inter-esterified to give a product with proper plastic property. These products need to have a proper solid fat content (SFC) or solid fat index (SFI) profile so that they maintain good integrity or firmness at room temperature, resist temperature cycling (i.e., repeated room temperature use and refrigeration storage), and melt completely at body temperature.

Various methods of laboratory scale, pilot plant processing, and batch reaction were described by Erickson. List *et al.* pioneered the development of a zero *trans* margarine by inter-esterifying 80% RBD (refined, bleached, and deodorized) soybean oil with 20% fully hydrogenated RBD soybean oil. The resulting product has SFI comparable to the conventional products.

Soybean oils with elevated levels of saturated fatty acids (by genetic modifications) can be randomized to produce margarines with desirable physical properties. A similar study of zero-*trans* margarine from soybean oils with modified fatty acid composition was conducted by List and co-workers.

Crystallization and Fractionation

Fractionation or winterization is a process in which the more saturated molecular species in the oil are solidified during low-temperature treatment and subsequently removed; cold storage stability is thereby increased. When partially hydrogenated soybean oil is fractionated, the more saturated molecular species are removed to produce a clear oil that meets the requirements of a salad oil and a high-stability liquid oil.

Table 5 Effect of processing on content of tocopherols, sterols, and squalene in soybean oil

Processing and Utilization of Co- or By-Products of Oil Refining

Soy Lecithin

Gum obtained from degumming of crude soybean oil is the predominant source of lecithin for pharmaceutical and food industries because of its availability and outstanding functionality. Crude lecithin contains a large amount of neutral oil and it is usually de-oiled to improve its functionality. This separation is based on the solubility difference of neutral and polar lipids in acetone. PLs are precipitated from acetone solution and separated. The three major classes of PLs in soybeans are phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylinositol (PI).

For certain applications, such as in pharmaceutical, nutritional supplement, and cosmetic industries, lecithin product with very high PC content is desired. Alcohol fractionation of deoiled lecithin provides alcohol-soluble and alcohol-insoluble fractions enriched with PC and PI, respectively. The PC-enriched fraction is an excellent oil-in-water emulsifier. The PI-enriched fraction is a good water-in-oil emulsifier often used in the chocolate industry to increase the viscosity of the mass, therefore reducing the need for cocoa butter. The typical composition of these lecithin products is shown in Table 6.

Soybean lecithins can also be chemically altered to modify their emulsifying properties and to improve their dispersibility in aqueous systems. PLs may be hydrolyzed by acid, base, or enzyme (phospholipase A) to achieve better hydrophilic and emulsification properties. Hydroxylation of lecithin improves its oil-in-water emulsification property and water dispersibility. Acetylation creates improved emulsification and water dispersion.

Soybean Tocopherols and Phytosterols

Soybean deodorizer distillate (SBDD) is the material collected from the steam distillation of soybean oil. It is a mixture of FFAs (particularly during physical refining), tocopherols, phytosterols and their esters, hydrocarbons, and secondary lipid oxidation products. The quality and composition of SBDD depends on feedstock oil composition and on processing conditions. Tocopherols and sterols are valuable components that can be further separated from the distillate and used in the nutrition-supplement and pharmaceutical industries. Table 7 shows the composition of deodorizer distillates from soybean and other vegetable oils.

Soybean tocopherols are the major source of natural fat-soluble antioxidants and vitamin E. There are at least four types of tocopherols in soybean oil. The γ-tocopherol is the major tocopherol present in soybean oil with the δ-, α-, and β-compounds present in decreasing quantities (Table 8). The table shows tocopherol composition of soybean oils obtained by conventional solvent extraction and mechanical press, in comparison with that of crude wheat germ oil.

Phytosterols are used as raw materials for over 75% of the world's steroid production. The more recent application of phytosterol and phytostanol and their fatty acid esters in margarine and table spreads is related to the cholesterol-lowering effect of these compounds. Hicks and Moreau (2001) have reviewed the recent development of functional foods containing phytosterols.

Soap Stock

Soap is recovered from alkaline neutralization of the crude or degummed soybean oil. It can be acidulated to produce acid oil, which contains FFAs, neutral oil, PLs, unsaponifiable matter, proteins, and mucilaginous substances. Soap stock is the lowest-priced by-product from oil processing and is generated at a rate of ~6% of the volume of crude oil refined amounting to as much as 1.8 billion pounds (0.9 Mt) in the United States annually. Most of the soap stock or the acid oil is used as feed currently.

Table 6 Typical composition (%) of commercially refined lecithin products

	Lecithin

Soybean oil methyl esters can also be produced from soap stock for biodiesel application.

Oxidative Quality of Soybean Oil

Soybean oil is a polyunsaturated or linoleic type of oil that is highly susceptible to lipid oxidation. The mechanism of lipid oxidation and lipid hydroperoxide breakdown has been discussed thoroughly by Frankel. Briefly, lipid auto-oxidation is a free radical chain reaction that involves the initiation, propagation, and termination steps. The primary oxidation product is lipid hydroperoxides. Decomposition of the primary product leads to a range of secondary oxidation products, of which some are off-odor and off-flavor compounds.

Oxidative instability limits the use of soybean oil in certain applications, but hydrogenation and other means of composition modification have made soybean oils the most widely used of all vegetable oils. The following analytical methods are frequently used to quantify oxidation of soybean oil.

"Sensory evaluation" provides information most closely associated with the quality of food lipids. Flavor or odor defects may be detected by panelists before they are recognized by chemical or instrumental methods. For example, the "fishy" and "grassy" taste produced in linolenic-acid-containing oils such as soybean oil occurs at very low levels of oxidation that are only detected by sensory analyses. The limitations of this method are poor reproducibility and high cost for panelists and the necessary facilities. The recommended approach is to use more reproducible chemical or instrumental methods to complement or support the sensory analyses.

"Peroxide value (PV)" is the most commonly used measurement of lipid oxidation. The standard iodometric method requires a relatively large sample size (5 g) when the lipid is only slightly oxidized. The ferric thiocyanate method based, on the oxidation of ferrous to ferric ion, involves colorimetric measurement of ferric thiocyanate. This method is more sensitive than the iodometric method and requires a relatively small sample (0.1 g). The PV is a useful measure for samples with low levels of oxidation and when the hydroperoxides are not decomposed. During prolonged oxidation, a maximum PV is reached and the value then begins to decrease due to peroxide degradation.

"Carbonyl compounds" in oxidized lipids are the secondary oxidation products resulting from the decomposition of the hydroperoxides. They can be quantified by the reaction with 2,4-dinitrophenylhydrazine and the resulting colored hydrazones are measured spectrophotometrically at 430–460 nm. The carbonyl value is directly related to sensory evaluation, because many of the carbonyl molecules are those responsible for off-flavor in oxidized oil. The anisidine value is a measure of carbonyl compounds that have medium molecular weight and are less volatile. It can be used to discover any prior oxidation or processing history of an oil.

"Conjugated diene hydroperoxides" produced from polyunsaturated lipids can be determined quantitatively by their strong absorption at 234 nm. This is a sensitive method, but it can only apply to the undegraded hydroperoxides.

"Gas chromatographic (GC)" methods have been used for determining volatile oxidation products. Static headspace, dynamic headspace, or direct injection methods are the three commonly used approaches. Each method produces significantly different GC profiles.

"The oxidative stability" of lipids has been evaluated by a variety of methods under a wide range of conditions. Temperature is the most important factor to consider in oxidative stability determination, because the rate of oxidation is exponentially related to temperature increase. Therefore, the shelf life of a lipid decreases logarithmically with increasing temperature. The mechanisms of oxidation and peroxide decomposition are different at different temperatures. Therefore to realistically predict oxidative stability of food lipids, the test conditions should be as close as possible to those under which the lipid is stored.

Storage at ambient conditions or at slightly elevated temperatures and measurement of weight gain, flavor, peroxide value, conjugated diene, or carbonyl compounds are commonly used to study oxidative ability.

Food Uses of Soybean Oil

According to Agricultural Statistics 2000, margarine, shortening, and salad/cooking oils accounted for 12%, 31%, and 41%, respectively, of total domestic consumption of oils and fats in the United States in 1998. Soybean oil was used to produce 95% of the total margarine and 83% of the total shortening. Based on 1998/99 soybean utilization in the United States (Golbitz, 2000), 95% of the total soybean oil produced was used in food applications. Among the food uses, 13%, 38%, and 48% of the soybean oil was used in margarine, shortening, and cooking oil, respectively.

Cooking and Salad Oils

Salad oil is a refined or sometimes fractionated liquid vegetable oil remaining liquid at 4.4°C. An important distinction between salad and cooking oils is the difference in their oxidative and thermal stability. Cooking oil is more stable than salad oil at higher temperatures such as deep-fat frying. Fully refined soybean oil can be directly used as salad oil, whereas other oils, such as sunflower and corn, have to be dewaxed before they can meet the criteria of a salad oil. Because soybean oil contains a relatively high amount of the polyunsaturated and unstable linolenic acid, it is usually partially hydrogenated to produce salad or cooking oils. Synthetic antioxidants – such as butylated hydroxyanisole (BHA), butylated hydroxy toluene (BHT), propyl gallate (PG), ascorbyl palmitate, and tertiary-butyl hydroquinone (TBHQ) – have been used in cooking oils. Natural antioxidants derived from sage, rosemary, and green tea are increasingly used to meet consumer's preference of natural food ingredients.

New nutrition-oriented salad and cooking oils are being developed. LoSatSoy is a low-saturated fatty acid oil developed at Iowa State University and commercialized as a salad and cooking oil. It has half of the saturated fatty acid compared with commercial soybean oil; therefore, it is believed to have nutritional benefit. Another newly developed oil is low-linolenate (1.2%; 18 : 3) soybean oil, which has improved oxidative stability in salad and cooking oil applications.

A unique vegetable oil, diacylglycerol oil, developed and successfully marketed in Japan by Kao Corp, is being produced from soybean and/or canola oil by an Archer Daniels Midland Co. (ADM) – Kao LLC joint venture. This oil is metabolized differently from other oils in that it is not stored as body fat but immediately burned as energy.

Margarine and Shortening

The traditional margarine is in stick form. Other forms, including spreadable, polyunsaturated, and low-fat margarines, have been developed to satisfy the demands of convenience and nutrition. A significant recent trend is away from margarine (80% fat, as defined by the FDA Standard of Identity) to spreads with less fat.

The most important functional properties of margarines and spreads are spreadability, oiliness, and melting property. Spreadability can be predicted by SFI and penetration measurement. Oil-off refers to the phenomenon when fine fat crystals no longer form a stable network to trap the liquid oil. Melting property depends on fatty acid composition and crystallization form.

Shortening contains 100% fat of vegetable or animal source and is used in frying, cooking, baking, and other confectionary items. It can be in plastic and semisolid or pourable fluid form, or in encapsulated powder, pellet, or flake form. It is produced by formulating a blend, solidifying and plasticizing the blend, and packaging and tempering. The β' form crystals are preferred for both margarine and shortening products. The large number of minute air bubbles incorporated in the shortening improves the leavening of baked foods. A more in-depth discussion of the science and technology of shortening has been presented by Metzroth.

Mayonnaise and Salad Dressing

The official definition (FDA Standard of Identity) describes mayonnaise as a semisolid food prepared from vegetable oil (no less than 65%), egg yolk, and vinegar. Most mayonnaise in the United States contains 75–82% oil which is usually soybean oil. The production of mayonnaise is partly an art due to the difficulty of producing the o/w emulsion in which the dispersed phase is much more than the continuous phase. Egg solids and processing conditions play critical roles in mayonnaise quality.

Salad dressings were developed as an alternative to mayonnaise. The standard of identity requires that salad dressing contain not less than 30% vegetable oil, vinegar, not less than 4% egg yolk, and is thickened by starch. Pourable salad dressing can be in two different finished forms: one phase or two phases depending upon whether the product is homogenized.

The oils used in salad dressing are selected using the same criteria as for mayonnaise.

The oil used in these products is predominantly soybean oil in the United States. Canada and Europe may use different oils depending on the availability of vegetable oil in that specific region.

Soy Concentrates and Isolates

C-Y Ma, The University of Hong Kong, Hong Kong, People's Republic of China

Introduction

With the continuous escalation in the cost of farmland and feed, food manufacturers are seeking low-cost, efficient protein sources to replace animal proteins. While crops and grains can provide a nutritive source of proteins in the diets of people in many developed and developing countries, the complete or partial replacement of animal protein, particularly in fabricated foods, remains a major challenge. This is due to the fact that the protein ingredient has to provide not only the calorie and nutrients to the products, but also the desirable organoleptic and functional properties required by the consumers. Of all the potential sources of unconventional food proteins, soybeans rank at the top of the list. Soy proteins are found in a large variety of food items, mainly in two categories: traditional soyfoods (e.g., soy milk, tofu, soy sauce), which use whole soybeans as the raw material, and formulated foods in which concentrated forms of soy protein are used as an ingredient. In the second category, a wide range of food items is represented, such as comminuted meat products, meat analogs, whipped toppings, frozen desserts, beverages, coffee whiteners, soups and sauces, pizza toppings and taco fillings, and bakery products.

Soy concentrates and soy isolates are concentrated forms of soy proteins extracted from soybeans after the removal of oils and other non-protein components. They are the by-products of oil processing in which soybeans are separated into oils and meals. The defatted meals have been used mainly as animal feed, but a significant portion of the meals is processed into soy concentrates and isolates for use as food.

Production

Soy concentrates and isolates, more commonly known as soy-protein concentrates and soy-protein isolates, are produced from de-hulled and de-fatted soy flakes or flours after the extraction of oils and fats. Figure 1 shows the typical manufacturing procedures for producing soy-protein concentrates. Soy-protein concentrates are produced from the de-fatted flakes by removing most of the water-soluble, low-molecular-weight components, mainly sugars. Three processes are used commercially to prepare concentrates. In the first process, nonprotein constituents are extracted with aqueous alcohol. In the second procedure, major proteins are insolubilized by dilute acid at pH 4.5 (the isoelectric point of soy proteins). There is some loss of acid-soluble protein in this process. In the third process, the flakes or flours are heated with moisture to denature and insolubilize the proteins, and the low-molecular-weight components are extracted with water.

Soy-protein isolates are produced from de-fatted soybean flakes by removing both the water-soluble sugars and water-insoluble polysaccharides. Figure 2 shows a typical flow diagram for the production of commercial soy-protein isolates. De-fatted flakes are extracted with either water or mild alkali (pH 7–9) at 50–55°C. The protein extract is separated from the insoluble residue (polysaccharides and residual protein) by screening, filtering, or centrifugation. By adjusting the pH to ~4.5 with food-grade acid, the major proteins are precipitated. The protein curd can be separated from the solubles (whey) by filtering or centrifugation. Spray-drying of the curd produces the isoelectric soy protein, whereas neutralization followed by drying yields the soy proteinates, which are preferred due to higher water-dispersibility and hence better functionality as a food ingredient.

Soy-protein concentrates and isolates can also be prepared by membrane processing using ultrafiltration (UF) and reverse osmosis (RO). In a patented procedure, de-fatted soybean flakes are extracted with water adjusted to pH 8–9 by calcium or sodium hydroxide at 43°C for 40 min. The material is centrifuged to remove the fiber and passed through a 70 kDa molecular-weight cutoff membrane. The retentate protein fraction is concentrated by RO and spray-dried. The permeate, containing soluble sugars, minerals, and small protein molecules, may also be concentrated by RO and spray-dried. The advantages of membrane processing are the ability to recover soy proteins without alkali solubilization – acid precipitation causing protein damage, the opportunity for removing undesirable components such as phytates, the potential to recover small proteins (12–20 kDa molecular weight) by using smaller-pore-size membrane, and the reduction in water consumption and processing discharge.

Chemical Compositions and Nutrient Contents

Proximate Compositions

Table 1 shows the proximate compositions of de-fatted soy flakes, three types of soy-protein concentrates, and soy-protein isolates. Despite the use of different manufacturing procedures, the overall

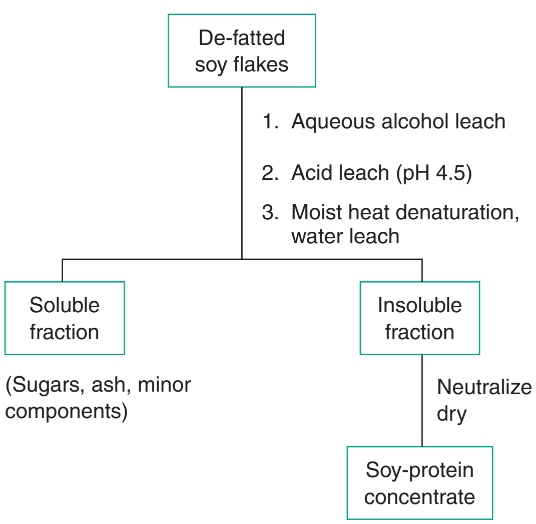

Figure 1 Typical processes for the production of soy-protein concentrates.

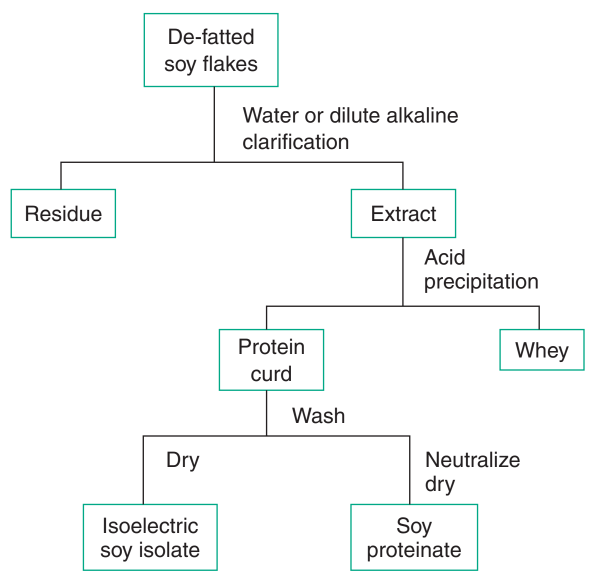

Figure 2 Typical process for the production of soy-protein isolates.

Table 1 Proximate composition of soy-protein products (% dry basis)

	Protein (N × 6.25)	*Fat (Pet. ether)*	*Crude fiber*	*Ash*	*Carbohydrates (by difference)*
Defatted soy flour	54	1.0	3.5	6.0	38
Soy-protein concentrate					
Alcohol leach	66	0.3	3.5	5.6	24
Acid leach	67	0.3	3.4	4.8	24
Moist heat, water leach	70	1.2	4.4	3.7	21
Soy-protein isolate	92	0.5	0.3	4.5	2.5

Table 2 Mineral contents of soy-protein products (dry basis)

Element	*Defatted soy flour*	*Soy-protein concentrate*	*Soy-protein isolates*
Calcium	0.22%	0.22%	0.18%
Chlorine	0.13%	0.11%	0.13%
Chromium	0.9 ppm	<1.5 ppm	<1.0 ppm
Copper	23 ppm	16 ppm	12 ppm
Iodine	0.01 ppm	0.17 ppm	<10 ppm
Iron	110 ppm	100 ppm	160 ppm
Magnesium	0.13%	0.25%	380 ppm
Manganese	28 ppm	30 ppm	17 ppm
Phosphorus	0.68%	0.70%	0.76%
Potassium	2.37%	2.1%	960 ppm
Sodium	254 ppm	50 ppm	1.1%
Sulfur	0.25%	0.42%	
Zinc	61 ppm	46 ppm	40 ppm

compositions of the three soy concentrates are similar, with the protein content (on dry basis) ranging from 66% to 70%. The major nonprotein components are polysaccharides, including arabinan, arabinogalactin, cellulose, lignin, and pectin-like polysaccharides. Proteins in the alcohol-leached and moist-heat-treated water-leached concentrates are denatured and insoluble, and the acid-leached proteins are more soluble, making the concentrates more suited in food applications. Protein contents of commercial soy-protein isolates are typically over 90% (dry basis) using a nitrogen-to-protein conversion factor of 6.25 (assuming a nitrogen content of 16%), a commonly used ratio in the food industry. This factor is considered too high since nitrogen contents of purified acid-precipitated soy proteins are higher than 16%.

Mineral Contents

Table 2 shows the mineral compositions of various soy-protein products. All soy-protein products contain minerals – such as calcium, iron, copper, phosphorus, and zinc – in nutritionally significant amounts. In whole soybeans, however, much of the mineral content is tied up in the form of phytates by forming complexes with phytic acid and fibers, hence lowering their bioavailability. In human studies, ingestion of soy concentrates did not result in any unfavorable trends in calcium, magnesium, zinc, or iron assimilation. Other studies show that zinc availability in humans is high when isolated soy proteins are present in diets containing adequate zinc contents. The availability of iron from soy isolates added to meat is lower, but can be compensated by increased iron content of the product.

Essential Amino-Acid Contents

Soybeans and other legumes are considered an excellent source of dietary proteins, and the amino-acid profile of soy proteins is recognized as the most complete of all vegetable protein sources. With the exception of sulfur-containing amino acids (methionine and cystine), the amino acid pattern of soy proteins resembles that of the high-quality animal proteins.

Table 3 Essential amino-acid content of soy-protein products and suggested patterns (FAO/WHO) for amino-acid requirements (mg per g protein)

Essential amino acid	*Age*			*FNB pattern*	*Protein concen-trates*	*Protein isolates*
	2–5	*10–12*	*Adult*			
Histidine	19	19	16	17	25	28
Isoleucine	28	28	13	42	48	49
Leucine	66	44	19	70	79	82
Lysine	58	44	16	51	64	64
Methionine + cysteine	25	22	17	26	28	26
Phenylalanine + tyrosine	63	22	19	73	89	92
Threonine	34	28	9	35	45	38
Tryptophan	11	9	5	11	16	14
Valine	35	25	13	48	50	50

Table 3 shows the essential amino-acid compositions of soy-protein concentrates and isolates. When compared with the patterns for amino-acid requirements suggested by the 1980 Food and Nutrition Board (FNB) and the 1985 Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO), the soy-protein products meet or exceed these guidelines. This demonstrates that isolated soy protein is a complete and adequate protein source for humans. Hence, soy concentrates and isolates can be blended or used interchangeably with other high-quality proteins.

Nutritional Quality and Health Benefits of Soy-Protein Products

Protein Digestibility

Both animal tests and human clinical studies have shown that soy-protein products are comparable in digestibility to other high-quality proteins such as meat, milk, fish, and egg. In animal feeding experiments with rats and young pigs, the digestibility values of soy isolates and casein were similar. Studies with infants and young children demonstrated that the digestibility of different soy isolates were equal to or greater than that of milk proteins. Studies with young adult males showed identical digestibility values for isolated soy and meat proteins. The digestibility values of soy-protein concentrates and isolates range from 91% to 96%, comparable to that of milk.

Protein Efficiency Ratio (PER)

Small animal tests, particularly the protein efficiency ratio (PER) assay, have been used extensively to evaluate the nutritional quality of food proteins. The PER values of soy concentrates range from 2.0 to 2.2, and for soy isolates from 1.1 to 1.7, considerably lower than the PER value (2.50) corrected to casein. However, by supplemented soy-protein products with 1.5% methionine, the limiting essential amino acid in soy proteins, the PER values of soy concentrates and isolates can be increased to above 2.5 and 2.0, respectively.

Antinutritional Factors

Similar to many plant sources, soybeans contain a number of antinutritional factors that can influence its acceptability for food applications. These include protease inhibitors, hemagglutins, phytic acid, and lectins. Inhibitors of proteolytic enzymes – such as trypsin, chymotrypsin, carboxypeptidase, and elastase – lower the nutritional quality of soy protein. Trypsin inhibitors are the most important inhibitors in soybeans and two of them, the Kunitz and the Bowman–Birk inhibitors have been purified and studied in details. Both inhibitors cause enlargement of the pancreas in rats and chicks. Growth depression and pancreatic hypertrophy have been attributed to endogenous loss of essential amino acids in the enzymes secreted by the hyperactive pancreas in response to the inhibitory effect of the inhibitors. Although the significance of trypsin inhibitors to human health is not yet resolved, they should be eliminated from the diet.

Hemagglutinins cause clumping of red blood cells (hemagglutination) in *in vitro* tests. The major hemagglutin in soybean is a glucoprotein with a molecular weight of 110 kDa, and has been shown to inhibit the growth of rats.

Both trypsin inhibitors and hemagglutins can be easily inactivated by heat. Since the production of de-fatted soybean flakes and flours involved heating, soy-protein concentrates and isolates contain only low levels of these inhibitors. Only 3% of original hemagglutinin is retained in unheated isolates, which is eliminated in normal heating steps. Similarly, normal processing conditions lead to ~70% reduction in trypsin inhibitor in isolated soy protein. Additional heat treatments result in further lowering in trypsin inhibitor activity to a level that does not cause health problems in both animals and humans.

Health Benefits of Soy Proteins

Recent studies have demonstrated the positive influence of soy proteins on human health. These include lowering of blood cholesterol, prevention of cancer, diabetes and obesity, and protection against kidney and bowel diseases.

High level of plasma cholesterol, particularly low-density lipoproteins (LDLs), increases the risk for cardiovascular diseases. Both animal feeding tests and human clinical trials have shown that consumption of diets rich in soy proteins lowers serum cholesterol and the ratio of LDLs to high-density lipoproteins (HDLs), a beneficial form of cholesterol. It has been suggested that the 7S subunit of soy protein can activate LDL receptors in human liver and lower plasma cholesterol by a mechanism different from that proposed for other diets and hypolipolemic drugs.

Epidemological studies have suggested that soy protein may be protective for cancer risks. However, the cancer preventive effects may be related to non-protein components in soy-protein products such as dietary fibers and isoflavones. Many soy-protein products are rich sources of dietary fibers, which are known to decrease incidence of colon cancer. Isoflavones such as genestein are known as phytoestrogens, which can reduce circulating ovarian steroids and adrenal androgens and increase menstrual cycle length. Such effects may account for the decreased risk of breast cancer. Dietary fibers and isoflavones have other health beneficial effects, particularly when combined with soy proteins, e.g., lowering of serum cholesterol and modulation of glucose metabolism.

By providing a high-quality protein in concentrated form, soy concentrates and isolates can be used in specially designed low-calorie and high-nutrient-density meals. These can be used for weight reduction in obese subjects.

When compared to proteins from other food sources such as milk, seafoods, and nuts, soy proteins rarely incite allergenic responses in humans due to immune reactions. Soy-protein products can, therefore, be used in infant formula as an alternative protein source to replace milk proteins for infants allergic to milk proteins.

Functional Properties and Food Applications of Soy Concentrates and Isolates

Functional properties of food proteins are properties that affect their utilization in food systems. Soy proteins possess unique functional properties, which combined with relatively low cost, make them the most widely used protein ingredients by the food industry. Table 4 lists some examples of the food applications of soy protein products and the functional properties that are critical in these applications.

Solubility

Solubility plays an important role in many food applications for proteins, including beverages, food emulsions, and foams. Commercial soy-protein products exhibit a wide range of solubility highly dependent on pH and other components such as salts and sugars. Denatured proteins, found in soy concentrates prepared by alcohol leaching or moist heat treatment, have lower solubility than native proteins.

Water Hydration and Binding

Solubility, hydration, and water absorption or binding are different manifestations of protein–water interactions. Hydration or water absorption is a critical initial step in imparting the desired functionality to soy proteins. Water binding is the ability of a protein matrix to expand and absorb water without solubilization. Commercial protein products have a wide range of water-binding capacity. Highly soluble protein powder absorbs little water, whereas insoluble dehydrated protein granules can rehydrate and bind up to 3–4 times their weight of water. Protein granules hydrate slowly and form lumps which need to be broken up by mechanical mixing.

Emulsification and Foaming

Emulsions and foams are two-phase dispersed systems, with a hydrophobic phase (oil droplets or air bubbles) surrounded by a continuous aqueous phase. By reducing the interfacial tension, soy proteins can act as a surface-active agent and reduce the energy required to create the large interfacial areas characteristic of foams and emulsions. Soy proteins have relatively high emulsification capacity and aid in the formation of oil-in-water emulsions. By forming a protective barrier at the oil–water interface, soy proteins can also stabilize the emulsion droplets, preventing their coalescence and breakdown. Soy-protein products are used extensively as emulsifiers in comminuted meats and in baked goods and soups.

Foaming properties of soy proteins are important in food systems such as whipped toppings, chiffon desserts, and angle cakes. Soy proteins do not form stable foams due to the presence of foam inhibitors, probably residual lipids, which can be removed by alcohol extraction. Various chemical modifications of such enzyme hydrolysis have been used to improve the foaming properties of soy-protein products.

Fat Binding

Soy-protein products are used in foods for two different purposes with regard to fat binding or absorption. In comminuted meat products, soy proteins promote fat binding and hence decrease cook loss and maintain dimensional stability in the cooked products. The mechanism of fat binding has been attributed partly to physical entrapment and is correlated with bulk density and particle size, with bulky samples

Table 4 Functional requirements of soy protein in different food products

Food product	*Required qualities*	*Functional properties*
Beverages	Flavor, emulsion stability, heat stability	Solubility, flavor binding, emulsion stability
Meats, sausages	Flavor, aroma, water and fat binding, texture	Flavor binding, water holding, fat absorption, emulsification, gelation or texturization
Whipped toppings, chiffon desserts, angel cakes	Foam density, foam stability	Foaming capacity, foam stability, solubility
Bakery products	Flavor, moisture retention, loaf volume, texture	Flavor binding, water holding, film formation, gelation
Aburages	Water and fat binding	Film formation, cohesion
Instant tofu	Texture, flavor	Gelation, bland flavor
Soups, gravies	Thickening	Viscosity, gelation

absorbing more oil. In emulsified meat products such as frankfurters or luncheon meat, fat binding by soy proteins may also involve emulsion formation and stabilization.

In bakery foods such as pancakes and doughnuts, addition of soy-protein products can prevent excessive oil absorption during frying. This may be attributed to the denaturation of soy proteins to form a fat-resistant barrier at the product surface.

Gelation and Viscoelastic Properties

Soy protein in solution can form a three-dimensional network or gel matrix upon treatments such as heat, alkali, or calcium ion addition. The gelation of soy protein contributes to the structure and texture of some food products, including comminuted meats and bakery products. The gel matrix provides a medium to retain moisture and fats, and binds to flavors and other components. It also contributes to unique mouthfeel such as chewiness to the products. Gelation of soy proteins in formulated foods is influenced by a number of factors including protein concentration, pH, and other components including salts, sugars, and lipids.

Soy protein in solution also contributes to viscosity, a measure of resistance to flow. Soy-protein slurries at moderately high concentrations (10–12%) have relatively low apparent viscosity. Treatments that induce the formation of protein aggregates or coagulum can increase viscosity and contribute to the viscoelastic properties (e.g., thickening) of some food products such as soups and sauces.

Film Formation

The film-forming ability of soy protein is desirable in food products such as aburage, frankfurters, and bologna. When a dough of soy flour–water is autoclaved, a film is formed on the surface. This film acts as a barrier to water and solvents and can be broken by grinding or slicing when the dough is washed. When shredded meat is mixed with egg white and soy concentrate or isolate, the protein forms a coat and facilitates drying of the meat fibers. The protein film slows down flavor loss in the dried meat particles, assists dehydration, and provides desirable texture in the rehydrated product.

Texturization

Soy-protein products can be texturized to form preset structure with unique textural properties which are not changed upon further processing. The texturized soy proteins are generally insoluble but can be hydrated and swollen. Texturized soy proteins are used as ingredients to make simulated meat products including seafood, poultry, and ground meat products.

There are several types of texturized soy-protein products prepared by different processes. Texturized soy concentrates are prepared by thermoplastic extrusion or steam texturization. Soy concentrates are mixed with water, colors, flavors, and other ingredients and fed to a cooker-extruder, heated under pressure, and then extruded. The dried products are in granular form and the composition is similar to the source material.

Structured soy concentrates are prepared by passing high-concentration (30–75%) protein slurry with low fat and carbohydrate contents through an extruder into different sizes and shapes. Structured soy concentrates possess a fibrous rather than spongy structure, and can be flavored to resemble meat or poultry products.

Texturized soy isolates are manufactured by thermal extrusion as described above, or by extruding an alkaline-denatured protein dope slurry through spinnerets into an acid–salt bath that coagulates the protein to form fibers, which are washed and stretched to increase strength. The fibers can be combined with binders to form fiber bundles and fat, flavors, color, stabilizers, and other ingredients can be added. Pressure is then applied to form the simulated meat products. Complete meat analogue products, including ham, turkey, bacon, and sliced beef, have been prepared from texturized soy isolates, and are marketed as vegetarian-type foods.

Specialty Soy-Protein Foods and Ingredients

Partially hydrolyzed soy-protein products are prepared by either acid/alkaline treatments or by proteolysis with enzymes such as pepsin, trypsin, and papain. The products have reduced molecular weight range of 3–5 kDa. The hydrolyzed soy proteins have functional properties superior to that of the native proteins, particularly improved acid solubility and enhanced foaming and emulsifying properties. They are used as whipping agents in confections, toppings and dessert mixes, and in acidic beverages. Completely hydrolyzed soy proteins prepared by acid or enzyme hydrolysis can be used as flavoring agents.

Soy-protein isolates are used in soy-based infant formulas. These are suitable for infants suffering from allergy against milk proteins or intolerance to lactose. Special formulas using soy-protein products are also developed and manufactured for older infants and for geriatric, hospital and postoperative feeding. Soy-protein products have also been used in infant cereals and baby foods to increase the protein content, particularly in rice- and wheat-based products.

Future Outlooks

Soy-protein concentrates and isolates are valuable food ingredients in many fabricated food systems by providing the functional performance and sensory quality desired by the manufacturers and consumers. They also provide a nutritionally balanced, relatively low cost and high-quality protein, which can be used either alone or in combination with other protein sources. New technologies to remove undesirable soy colors and flavors have been reported, allowing soy-protein-based products with improved organoleptic quality to be developed, even at high levels of usage. Various physical and chemical processes, such as extrusion and partial proteolysis, have modified the functionality of soy proteins and greatly expanded their utilization in new food products.

With increasing consumer awareness on the relationship between diet and health, and the nutritional advantages of soy-protein-based products, such as low calorie, high fiber, and low in saturated fats, the demand on soy-protein products will be increasing. However, it should be noted that expanded utilization of soy-protein products and the successful establishment of soy-protein industry would also depend on securing viable markets for other major components, and in the case of soybeans, it is mainly oil. Although soybeans have to compete with many oilseeds in the vegetable oil market, soy protein is facing much less competition from other plant sources including oilseeds and starchy crops, mainly due to its established market and well-developed technology.

Soy-Based Fermented Foods

D K O'Toole, City University of Hong Kong, Hong Kong, People's Republic of China

Soybean-based fermentations were developed in China and East Asia, and most depend on filamentous fungi that break down the proteins and carbohydrates, and yeasts and bacteria that produce flavor compounds. A small amount of added starch from starch-based grains promotes better microbial growth and flavor development. Products include those made with whole soybeans, with soymilk extracted from soybeans, and products that result in soybean pastes and condiments. The microbiological and biochemical processes involved in their production are now relatively well known and therefore pure microbial cultures are used in modern industrialized processes. In addition, with escalating soymilk production there is an increasing amount of "okara," a fibrous waste product that poses a waste disposal problem. Fermentations using traditional microorganisms can turn okara into useful human foods, and those using novel microorganisms have yielded novel bioactive compounds. For a long time soybeans have had a reputation for being beneficial to health and recent studies covering fermented soybean and fermented okara are discussed.

Introduction

Unlike other grains soybeans do not contain large quantities of starch, but they do contain large

amounts of good-quality protein and oil. However, the protein is not easily digested and so it must be made nutritionally available by the first step of soaking and cooking the beans. This step makes the protein more digestible and destroys the antinutritional characteristics of the soybeans. The oil plays little or no part in soybean fermentations.

In most food fermentations easily available mono- and di-saccharides, either as the sugars or as breakdown products from starch, are a prerequisite for the fermentation to proceed. In the case of soybean the amount of carbohydrate is ~30% in the dry matter and about a third of it is soluble (*see* **Nutrition**: Soy-Based Foods). The soluble component consists of sucrose (~5%), raffinose (~1%), and stachyose (~4%); the insoluble carbohydrate (~2% of the dry matter) is made up of starch (<1%), cellulose (~4%), hemicellulose (~1%), and pectin (~6%). In view of this composition soybean fermentations are sometimes augmented with small or large quantities of starch from other grains, because it promotes microbial growth. By far, the most important microorganisms for soybean fermentation are the filamentous fungi rather than bacteria or yeasts. The fungi produce a range of powerful enzymes capable of hydrolyzing protein, starch, and complex carbohydrates, and, despite low starch levels, acid-producing and proteolytic bacteria, as well as yeasts, often play a significant role.

Fermented Whole Bean Products

The gross composition of some fermented soybean products is shown in Table 1.

Tempeh

"Tempeh" is a fermented soybean product and meat substitute that originated in Indonesia. It is probably the first "fast food" in that it can be deep-fried in 3–4 min or cooked in 10 min. The production of tempeh is outlined in Figure 1 (*see* **Soybean**: Soymilk, Tofu, and Okara). In the first step the soybeans are soaked in water or acidified water at room temperature. During this stage a partial germination of the soybeans may occur depending on the amount of O_2 available to the seed, and acid is produced by bacteria growing in the soak water. Depending on the temperature during soaking, bacteria reach 10^8–10^{10} colony-forming units per ml after 24–36 h. The pH drops from ~6.5 to ~4.5 due to the growth of the acid-producing bacterial species – e.g., *Lactobacillus casei, Streptococcus faecium, Staphylococcus epidermidis*, and *Klebsiella pneumoniae* – that are present naturally on the soybeans. The acid helps to prevent the growth of undesirable microorganisms, but any partial seed germination can affect the protein properties of the soybean and the subsequent fungal growth

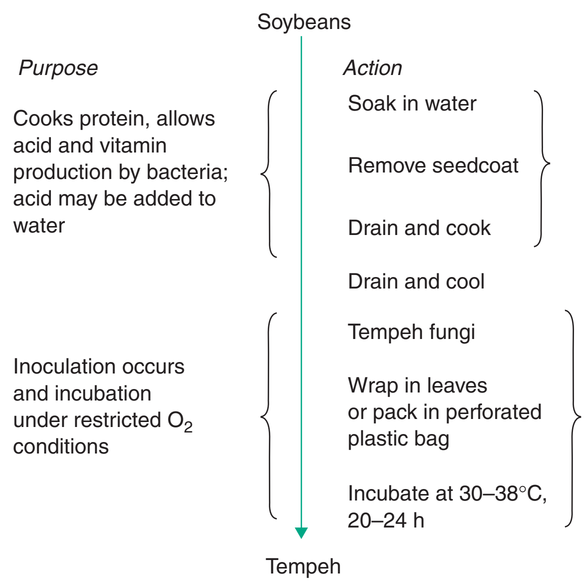

Figure 1 A flow diagram of the production of tempeh, an Indonesian fermented soybean product. The fungal mycelia knit the soybeans into a cake.

Table 1 The gross composition, g per kg, of some fermented soybean products

phase. The bacteria that grow in the steeping water produce vitamin B_{12}, a significant nutrient in tempeh. The most desirable bacterial species for this stage is *K. pneumoniae*, but other pure bacterial starter cultures can perform the same function.

The soaked beans are de-hulled and carefully cooked to avoid overcooking or undercooking of the beans. The soybeans are then drained, cooled below 35°C, and dusted with wheat flour to provide a good source of fermentable carbohydrate, and inoculated. The desirable fungal species for successful tempeh production, whether arising from environmental inoculation or from pure starter inoculation, are *Rhizopus oligosporus* (e.g., NRRL-2710), *R. stolonifer, R. arrhizus, R. oryzae, R. formosaensis*, and *R. achlamydosporus*. The spores of *R. oligosporus* are produced commercially in Indonesia for industrial-scale tempeh production. During the fungal growth phase the O_2 level must be controlled at a reduced level, otherwise the fungus will grow too quickly and form black spore masses that degrade the quality of the tempeh. The traditional way to control O_2 is to wrap the inoculated beans in banana leaves, but a modern innovation is the use of microperforated polyethylene plastic. The fungus grows and mycelia knit the beans into a firm cake to give the characteristic meaty texture.

The enzymes from the fungi transform the soybeans making them more nutritious by hydrolyzing the protein and complex carbohydrates and increasing the levels of the vitamins – riboflavin, niacin, pantothenic acid, and vitamin B_6. Tempeh must be consumed fairly quickly. Defects include: (1) black patches due to fungal sporulation, (2) slime due to excessive bacterial growth because of too little O_2 or a temperature of 42°C, and (3) a yellow color due to growth of toxic fungi. The yellow color indicates that the tempeh is highly toxic and it should not be eaten.

Natto

This is produced in Japan, Korea (“chung kook jang”), and Thailand (“thua nao”), but not in China. Traditionally the beans are soaked, boiled, and cooled and wrapped in rice straw and left for 1–2 days at a warm temperature to allow bacteria to grow on the beans and produce a sticky slime. The straw imparts a straw aroma to the fermented beans as well as being the source of the bacteria for the fermentation, and it absorbs some of the unpleasant aroma of ammonia released during the bacterial growth.

In modern manufacture, bacterial cultures of an obligate aerobe *Bacillus subtilis* var. *natto* are used, and the incubation temperature is kept at 38°C for

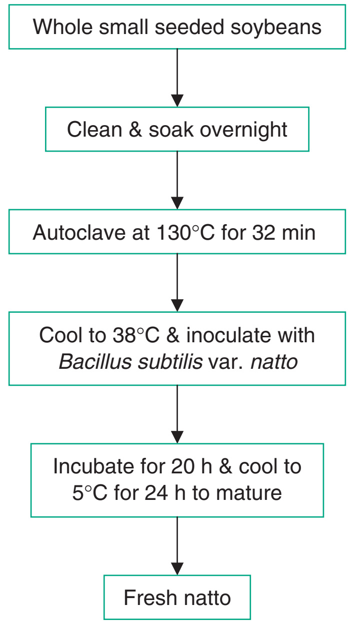

Figure 2 A flow diagram showing how natto is produced. (Adapted from Liu K-S (1997) *Soybeans: Chemistry, Technology, and Utilization*. New York: Chapman and Hall.)

20 h followed by cooling (Figure 2). During growth the bacteria produce a viscous, sticky slime that pulls out into long strings when the soybeans are pulled apart. The viscous substance increases to ~2% of the “natto” after 48 h and its crude protein content is ~80% of which ~20% is the D-isomer of γ-polyglutamic acid and the remainder is mostly free amino acids. The bacterial fermentation results in a high concentration of vitamin K_2 (menaquinone-7), 100 times more than found in cheese. The fermentation also reduces the “beany” flavor and aroma of soybeans and increases the level of alkyl pyrazines that are responsible for the characteristic odor of natto. The amount of volatile compounds rises from ~35 µg per kg wet weight in cooked soybeans to 2–3.5 mg per kg wet weight in 72 h. Predominant volatile compounds in Japanese natto are 3-hydroxybutanone (acetoin), 2,5-dimethylpyrazine, trimethylpyrazine, and tetramethylpyrazine.

Salted Black Beans or Soy Nuggets

This product is made in China (“douchi”), Japan (“hamanatto”), the Philippines (“tao-si”), and India (“tao-tio”). Whole soybeans are soaked and cooked as usual. Under natural conditions, fungi/bacteria grow that depend on the ambient temperature, but under controlled conditions an inoculum of *Aspergillus oryzae* is used. The Chinese incubate for 3–20 days and then wash the beans to remove fungal spores, mycelium, mold odor, and bitter taste, and

then mix them with brine (or soy sauce) and spices which can vary widely (e.g., Indians add sugar), and ferment in a jar for several months. They are then dried. The Japanese use a soybean : wheat flour ratio of 2 : 1 and incubate for 50 h. They do not wash the beans, but sun-dry them immediately and then place them in brine under pressure for weeks to months. They are then redried and soy-sauce-pickled ginger may be added at the final stage.

Soymilk-Based Products

Fermented Tofu

The general name for these products is "sufu" which means "molded milk" in Chinese, and in hieroglyphics it is known as "furu" which is its preferred Chinese name. Soymilk is extracted and coagulated to make a curd ("tofu") that is then cut into rectangular pieces on which mold is allowed to grow. Mold enzymes hydrolyze the protein, making it more digestible, and the soy oil, producing strong flavors. Tofu was invented by Liu An in ~179–122 BC and the first production record dates from the Wei Dynasty in AD 220–265, but the origins of "sufu" are not known. Sufu production in China, domestically and in factories, is ~300 000 t per annum.

The sufu making process is as follows (Figure 3). Soybeans of suitable quality are processed in the usual way to produce soymilk (*see* **Nutrition**: Soy-Based Foods and **Soybean**: Soymilk, Tofu, and Okara). The coagulation step involves addition to soymilk at 70–80°C (in a suitable container) of calcium sulfate or magnesium sulfate at a rate equal to ~2.5–3.5% of the dry weight of the soybeans used to produce the milk which is ~20% more than used to produce regular tofu. After briefly stirring the mixture vigorously, it is left quiescent for the coagulum to form in 10–15 min. The curd is then pressed mechanically to remove excess water (soy whey) and cut into rectangular blocks 32 × 32 × 16 mm. Moisture content and pH vary between 70–79% and 6–7, respectively.

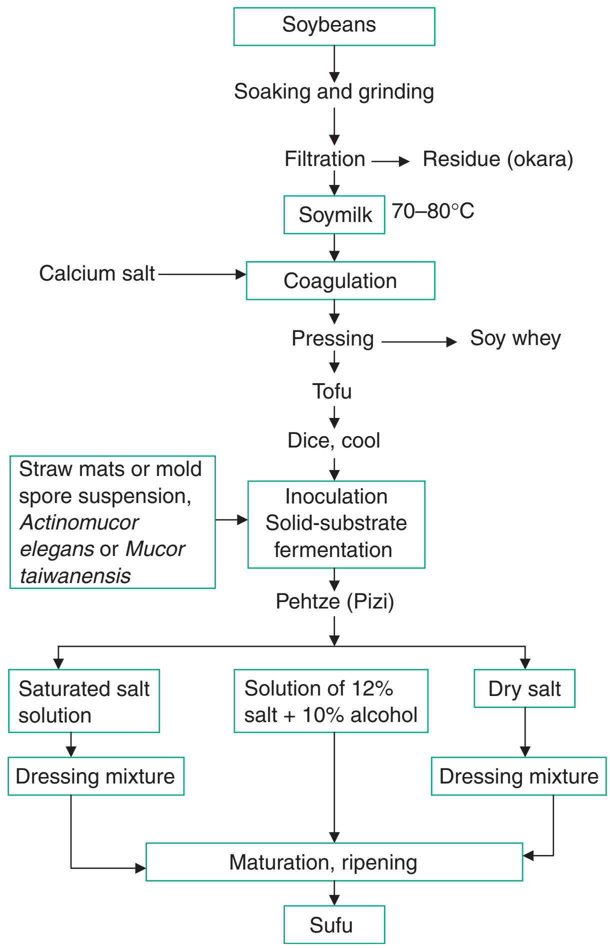

Figure 3 A flow diagram of the production of sufu, a kind of fermented tofu block. It depends on the growth of fungi on the surface of the tofu blocks to help in the production of flavors. Salting and dressing mixtures favor the development of flavors and introduce flavors to the final product.

Mold stage The next stage, the "pehtze" (pizi) or mold stage, is akin to the "koji" stage in soy sauce and "miso" production. Traditionally, the spores came from straw mats and contaminated the surface, but in modern production methods, spores of a selected pure fungal culture, first isolated and identified in 1920, are applied to the surface of the cubes followed by incubation. Using pure mold cultures, production time is reduced from 5 to 15 days to ~48 h. Preferred mold cultures include *Actinomucor elegans* and *A. taiwanensis* used in Beijing and Taiwan, respectively, but *Mucor sufu* and *M. wutungkiao* also have desirable characteristics. The mold for the production of the best-quality pehtze must have:

1. a high proteolytic and lipolytic activity;
2. white appearance, or at most a slight yellow color that is attractive to consumers;
3. the ability to produce a mycelial mat over the tofu surface with a texture that is dense and tenacious and able to retain the tofu block shape during subsequent processes; and
4. the ability to prevent unwanted bacterial growth, and the inability to produce off-odor, astringent taste, and mycotoxins.

Ideally temperature and relative humidity should be controlled for pehtze production, because *Actinomucor* and *Mucor* species only grow well in the 20–30°C range. The fungal starter culture, as a spore suspension containing ~10^5 colony forming units per ml, is

prepared either by solid-state or by liquid culture in roux bottles. The solid-state culturing medium is bran and water (1 : 1.3 or thereabouts) and the liquid culture medium is soy whey with added maltose (2–3%) and peptone (1.5–2.0%).

The tofu blocks are sprayed with the inoculum and placed on wooden or bamboo strips in plastic trays and transferred to an incubation room at ~25°C with relative humidity of 88–97%. Within 8–12 h a thin layer of mycelia is obvious, and by 36–40 h it is thick. The temperature is then reduced by aeration of the room and the pehtze observed regularly until a slight yellowish-white color appears. The total incubation time is ~48 h, but glutaminase activity that results in glutamic acid production and increased monosodium glutamate (MSG) levels is greatest within 3 days. In the final stage of pehtze production, the mold is flattened by hand.

Salting stage Salting does five things: it imparts a salty taste to the sufu, it prevents the growth of undesirable organisms, it stops the growth of the mold, it releases the proteolytic enzymes bound to the mold mycelia so they can penetrate into the tofu to transform it, and it removes some water from the tofu blocks. Salting can be by dry salting or brine salting. Dry salting takes longer and does not result in a consistent product. The layers of blocks are spread with dry salt, and then stored for 6–12 days during which the salt content of the blocks rises to ~16%. The blocks are then removed, washed with water, and transferred to another container for further ripening. Brining is done with a saturated salt solution, or an alcoholic brine solution in which the blocks are immersed for 4–5 days, resulting in final moisture levels of 50–65% with ~12% salt. The alcoholic brine combines the salting and aging or ripening steps. The ethanol has two effects: first, during ripening lipolytic enzymes release free fatty acids that combine with ethanol to produce aromatic esters, and second, it seems to interfere with protein degradation when compared with salted sufu so that the sufu does not degrade as much.

The final ripening stage of dry salted pehtze is conducted in various dressing mixtures that result in a range of different sufu products. The salted pehtze is placed in the dressing mixture in jars or bottles ranging in size from 0.25 to 10 l. For red sufu the dressing preparation commonly used is a mixture of 2% "angkak," 3–5% of a paste made with flour or soybean, 8–12% of alcohol, and 5–10% of spices. Further flavor variation is obtained by adding flavors such as rose essence for Rose Sufu or hot pepper to make a Hot Sufu. Traditional ripening periods extend up to 6 months, but modern methods require only 2–3 months. Reducing the size of the tofu cubes, lowering the salt content from ~14% to ~10%, lowering the alcohol content from ~10% to ~6%, keeping the ripening temperature higher and constant, and reducing the storage jar size can further reduce the ripening period. The higher salt concentrations are thought to reduce rates of proteolysis and lipolysis, but reduced salt content shortens the shelf life.

Types of sufu Types vary widely throughout China, but four types are distinguished based on the fermentation methods used, and four types based on the color and flavor of the product. The four fermentation types are given as follows:

1. *mold-fermented sufu*: use of pure mold culture, brine salting, and aging in a dressing mixture;
2. *naturally fermented sufu*: use of environmental fungi in straw mats and the subsequent process is the same as for (1);
3. *bacteria-fermented sufu*: the tofu is prepared and presalted and a pure bacterial culture is used followed by further salting and aging; and
4. *enzymatically ripened sufu*: use of mold-based koji (see soy sauce) at the dressing stage.

From the dressing stage four color and flavor types of sufu are recognized; they are given as follows.

1. *Red sufu.* Sufu blocks are red to purple outside and yellow to orange inside due to the angkak ("anka," red kojic rice or red "qu") prepared with the fungus *Monascus purpureus* that also imparts a specific flavor to the sufu.
2. *White sufu.* Sufu blocks are a light yellow color throughout and manufacture is similar to red sufu but without angkak and with a slightly reduced salt content.
3. *Grey sufu.* It has a strong pungent odor basically of unknown origin. It is probably derived from the use of a dressing mixture that includes soy whey from the soymilk manufacturing step, as well as salt and spices.
4. *Other sufu.* Sufu blocks are flavored with a variety of additives including vegetables, rice, bacon, and higher concentrations of alcohol.

Sufu may be further classified by size and shape.

Soymilk Yogurt

This is a modern product intended to imitate yogurt but the beany flavor due to natural *n*-hexanal and pentanal, and stachyose and raffinose, that cause human flatulence, detract from the product. Trials with the usual yogurt cultures did not produce

good results unless lactose or sucrose were added. However, *Bifidobacterium bifidum* can metabolize the sugars and the bean flavor substances to produce a satisfactory product thought to be beneficial to human health.

Fermented Soybean Pastes

Soy Sauce

Soy sauce is an ancient Chinese product whose precursor was mentioned ~3100 years ago in the Chinese literature. It was introduced to Japan in AD 552 and has also spread to other East Asian countries (Table 2). Soy sauce was derived from a Chinese food called "chiang yu" that was basically a mash made by growing yellow aspergilli on millet then mixing the molded grain and salt in an alcoholic liquor with added pieces of animal, poultry, or fish flesh and storing it for 100 days. (A similar product using soybeans is still made today in China.) A liquid extract from this type of product was first mentioned in the Han dynasty (AD 25–220) and the first mention of the use of soybeans in this kind of mash dates from AD 535. However, it is the Japanese who have established the scientific basis for modern soy sauce production and they call it "shoyu." In AD 2000 ~1800 manufacturers in Japan produced 1.046 million kiloliter (Mkl) of soy sauce of which 51% was produced by six manufacturers.

The best-quality soy sauces are naturally brewed but in practice some commercial soy sauces may contain added vegetable protein extract prepared by chemical or enzymatic hydrolysis. Briefly, production involves an initial solid-state mold growth phase followed by steeping in brine solution. Soy sauce is the liquid extract from the aged mixture. The varieties of soy sauces on the market owe their differences to the countries of origin where different processing conditions are used, and to the addition of wheat, a source of starch that promotes fungal growth and the production of mold enzymes. The soybean : wheat ratios used vary from 1 : 0 to 1 : 3. In Japan there are five main types of shoyu – "koikuchi," "usukuchi," "tamari," "saishikomi," and "shiro" – based on the soybean : wheat ratios and other factors (Table 3).

Table 2 The general composition[a] of some soy sauces from various parts of the world

Product	*Bé*	*NaCl*	*TN*	*RS (IS)*	*Alcohol*	*Color*
Koikuchi shoyu, Japan	23.6	170	17	50.7	25	++
Soy sauce, Taiwan	25.6	156	20.5	59.5	8.6	++
Soy sauce, Korea	21.9	173	15	21	3.9	++
Soy sauce, Hong Kong	28.5	262	15.4	42.2	0	+++
Soy sauce, The Philippines	23.3	247	7.6	10.6	0.1	++
Soy sauce, Singapore	30.1	241	19.7	48.1	0	+++
Soy sauce, Malaysia	23.9	183	11.7	85	0.3	+++
Kecap asin, Indonesia		72	1.9	144.5	0.2	++
Kecap manis, Indonesia		59	1.9	111 (581)	0.9	+++
Soy sauce, USA	22.8	16.5	1.65	37	20.7	++

[a] Bé = specific gravity, Degrees Baumé; NaCl = sodium chloride ($g\,l^{-1}$); TN = Total nitrogen ($g\,l^{-1}$); RS (IS) = reducing sugar (invert sugar) ($g\,l^{-1}$); alcohol = ethanol ($ml\,l^{-1}$).
Adapted from Yokotsuka T and Sasaki M (1998) Fermented protein foods in the Orient: *shoyu* and *miso* in Japan. In: Wood BJB (ed.) Microbiology of Fermented Foods, vol. 2, 2nd edn., pp. 351–415. London: Elsevier Applied Science.

Table 3 Typical percentage composition of the five types of soy sauce recognized in Japan

Soy sauce (Shoyu)	*NaCl (w/v)*	*Total nitrogen (w/v)*	*Formol nitrogen (w/v)*	*Reducing sugar (w/v)*	*Alcohol (v/v)*	*Color*	*Soybean : wheat ratio*	*Comment*
Koikuchi	16.9	1.57	0.94	3	2.3	Deep brown	1 : 1	Most popular in Japan, 83% of market
Usukuchi	18.9	1.19	0.8	4.2	2.1	Light brown	More wheat	
Tamari	19	2.55	1.05	5.3	0.1	Dark brown	10 : 1	Main Chinese type
Saishikomi	18.6	2.39	1.11	7.5	Trace	Dark brown	1 : 1	Raw shoyu, not fresh brine, is used
Shiro	19	0.5	0.24	20.2	Trace	Yellow/tan	Very high wheat	

Specific gravity is from 22° to 29° Baumé; pH is from 4.6 to 4.8.
Adapted from Fukushima D (1989) Industrialization of fermented soy sauce production centering around Japan. In: Steinkraus KH (ed.) *Industrialization of Indigeneous Fermented Foods*, pp. 1–88. New York: Marcel Dekker.

Koikuchi is the most popular in Japan, and the main Chinese type of soy sauce is similar to tamari but soybean : wheat ratios of 2 : 1 and 1 : 1 are also common in China. Indonesians have two basic kinds of soy sauce – "kecap asin" and "kecap manis" – and they add sugar to the latter. Koikuchi has an alcohol content of 0.3% because it stabilizes the quality and adds flavor to shoyu, but ethanol is not a significant constituent in soy sauces from other parts of Asia. However, in taste tests, Koreans also favor ~3% ethanol in their "kanjang."

Raw materials and their preparation The first stage in koikuchi soy sauce production is the choice of raw materials (soybeans and wheat) and their preparation (Figure 4) (*see* **Nutrition:** Soy-Based Foods and **Soybean:** Soy Concentrates and Isolates). The traditional choice is whole beans and whole wheat grains and the beans are cooked and the wheat roasted and cracked. However, the oil content of the beans is insignificant in soy sauce, so in modern production systems defatted beans are used, as well as wheat flour. Wheat bran is sometimes preferred, because it is a source of ferulic acid, a precursor for 4-ethylguaiacol, a desirable flavor component. Also the pentose in wheat bran enhances darker coloration and color stability, but reduces the alcohol content. Best-quality soy sauces contain high soluble nitrogen levels, so one of the objectives of production is to maximize the extraction of the bean protein, which is achieved by using heating at far higher temperatures and for much shorter times than in the traditional boiling methods. Following preparation of the raw materials and cooling them, they are mixed and inoculated with fungi to make the koji. The most desirable fungi are strains of either *A. oryzae* or *A. sojae*.

Koji production The "tane" koji, or starter culture for the koji, is prepared by growing the molds through to the sporulation stage on steamed polished rice or wheat bran. Then ~0.1–1.0% w/w is mixed with the cooked soybean/wheat mixture. In traditional koji production, the inoculated soybean/wheat mixture is placed in a shallow layer (~3–5 cm) in trays in a koji room and incubated for 2–3 days for mold growth. The fungi require oxygen to grow and produce heat that must be dissipated (Figure 5), but in modern production systems special koji rooms or machines are used and conditioned air is mechanically driven through the inoculated layer of soybean/wheat mixture. The fungi produce amylase in the temperature range 35–40°C, but excessive

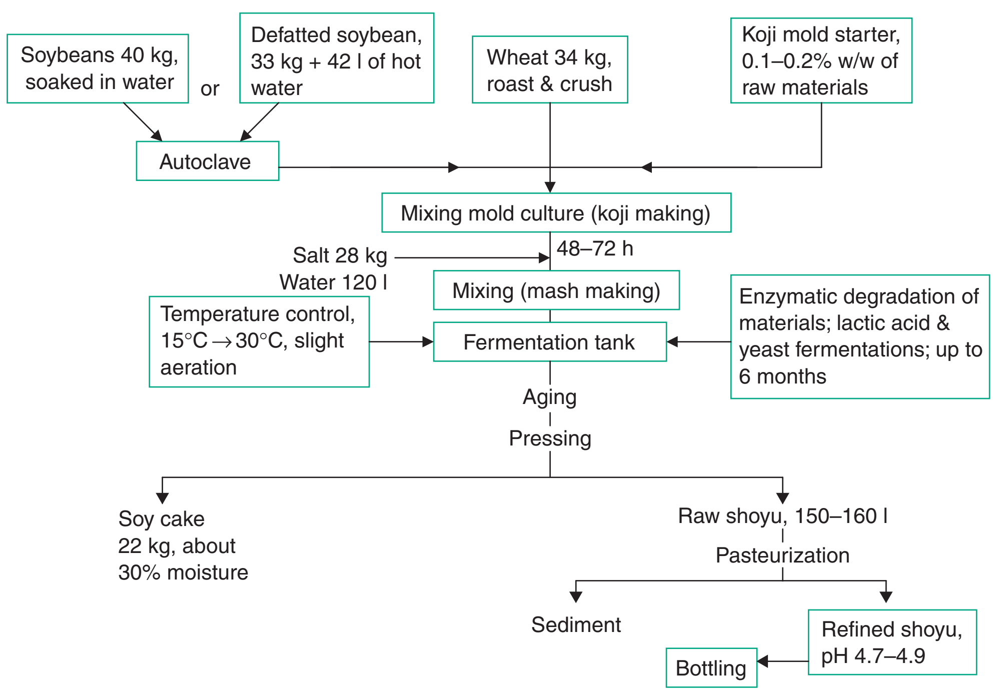

Figure 4 A flow diagram of the production of koikuchi shoyu, the most popular type of soy sauce in Japan. The product is a salty extract of the soybean : wheat mixture modified by mold growth through the mixture, followed by yeast and bacterial growth in the brine that results in distinctive soy sauce flavors. (Adapted from Yokotsuka T and Sasaki M (1998) Fermented protein foods in the Orient: *shoyu* and *miso* in Japan. In: Wood BJB (ed.) *Microbiology of Fermented Foods*, vol. 2, 2nd edn., pp. 351–415. London: Elsevier Applied Science.)

amylase production results in sticky koji so the koji must be cooled by mixing at around 18 and 27 h of incubation. Good ventilation is important; however, overcooling can be detrimental. The fungal growth slows at ~36 h, and during the last stage the important proteases begin accumulating below 35°C. The process is stopped before fungal spore formation by gathering up and placing the prepared koji in a brine solution for the long steeping stage.

The production processes and names of the processing stages differ from country to country (Table 4). In Korea, during traditional manufacture instead of koji, a "meju" cake is made. Soybeans are steeped for 24 h, de-hulled, steamed for 2 h, and cooled to 50°C, and then crushed to a size of 10–15 mesh and natural environmental mold allowed to grow. The molded soybean cakes are dried for 2 days in air and then hung up with rice straw for a further 20–30 days to ferment in a koji room. The cakes are then broken into ~12 pieces before immersion in brine. In Indonesia, the koji is sun-dried before steeping.

Moromi stage In the steeping stage the brine solution is made up with water low in iron and copper, adjusted to pH 6.5–7.0 and cooled to 0°C. A complex enzymatic and fermentation process begins that is controlled by managing the temperature, and the addition of air and pure cultures. The high sodium chloride concentration kills the fungi and other incidental salt-sensitive bacteria and yeasts in the koji. The fungal enzymes continue to break down the starch and proteins as well as cellulose, hemicellulose, and pectin in the soybeans (Figure 6). The objective during this stage is to maximize flavor production, release of proteins by hydrolysis of cell structural components by macerating enzymes (hemicellulase, pectinase, etc.), and protein hydrolysis. About 300 compounds contribute to flavor which depends on the sauce pH range being 4–5, but the important ones are glutamic acid (MSG) and ethanol, the characteristic soy sauce compound 4-hydroxy-2(or 5)-ethyl-5-(or 2)-methyl-3(2*H*)-furanone (HEMF), 4-ethylguaiacol, and 4-ethylphenol. Glutamic acid is produced early by the fungal enzymes and is maximized by retarding the growth of the lactic acid bacterium *Tetragenococcus halophilus* by keeping the temperature of the moromi low at ~15°C for the first few weeks. The ethanol production depends on the growth of a yeast, *Zygosaccharomyces rouxii*, but the yeast will only grow after the pH of the mixture has been reduced to

Table 4 The names by which the various stages of the soy sauce production system are known in some East Asian countries

Country	*Solid-state fermentation stage*	*Steeping stage*	*Final product*
Japan	koji	moromi	shoyu
Korea	meju		kanjang
Indonesia	bungkil	baceman	kecap
China	chou		chiang-yu
The Philippines			toyo
Thailand			see-ieu

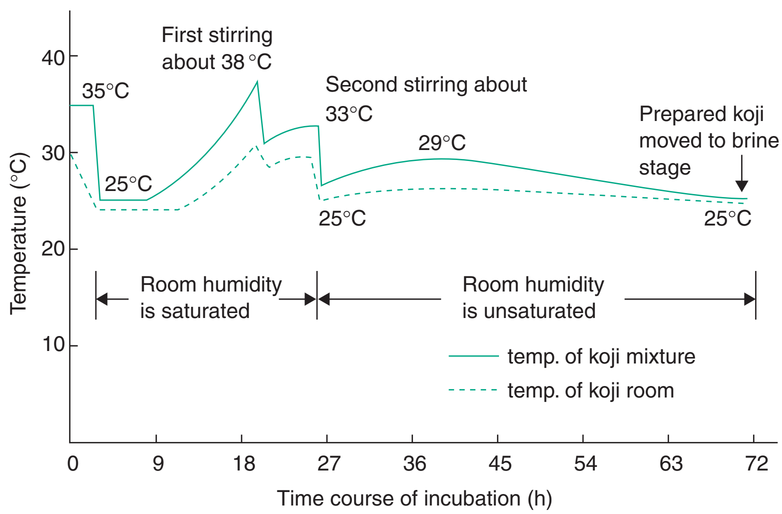

Figure 5 The production of koji is an aerobic process that depends on the growth of fungi. This illustrates what happens in a traditional process. The soybean : wheat mixture is inoculated and spread in a layer ~5 cm deep. The tray is then put in a controlled atmosphere room and as the fungus grows it produces heat. This heat must be dissipated to reduce temperature so the layer is mixed twice, as indicated. The koji is harvested before the mold starts to sporulate when enzyme production is optimum. (Adapted from Fukushima D (1989) Industrialization of fermented soy sauce production centering around Japan. In: Steinkraus KH (ed.) *Industrialization of Indigenous Fermented Foods*, pp. 1–88. New York: Marcel Dekker.)

< pH 5.0 by bacterial growth. To maximize ethanol production the moromi temperature is raised to 30°C below which ethanol production is almost nonexistent. Later other yeasts, *Candida versatilis* and *C. etchellsii*, grow and produce the other characteristic compounds, 4-ethylguaiacol and 4-ethylphenol, from ferulic and *p*-coumaric acids. All the yeasts are obligate aerobes; so to encourage their growth the moromi is stirred occasionally by pumping air to incorporate oxygen. The moromi maturation time in Japan is from 6 to 8 months. At the end of 2–3 months, most of the fermentable carbohydrate has been converted to lactate (1% w/v), ethanol (2–3% v/v), and simple sugars (e.g., glucose and xylose).

The length of the moromi stage in other countries varies. In Indonesia it may be from 1 day up to 5 months, in Korea the traditional incubation period is 2 months. In China one method used involves a defatted soybean meal : wheat bran mixture at a 6 : 4 ratio that is incubated for 24 h for koji production followed by 3 weeks at a moromi temperature of 40–45°C.

Finally, the solid and liquid components are separated, either by drawing off the liquid or drawing off and pressing the residue. In some parts of China, the raw soy sauce is drawn off and further brine is added to the residual beans for a short period to produce different grades of soy sauce. The raw sauce is placed in a vat exposed to sunlight under a transparent cover for up to 6 weeks. The raw liquid is then heated to develop further flavor compounds in the final product. The heating promotes Strecker degradation reactions and Maillard reactions involving pentoses and amino acids that produce flavors.

A biotechnological approach, to reduce the soy sauce production time by employing bioreactors based on immobilized enzymes and microbial cells using ceramics, chitopearl, and alginate gels as the base, has shown some promise. Production times as short as 2 weeks have been achieved. The koji mixture is produced as usual and the enzymatic hydrolysis stage in the brine is controlled. The hydrolyzed extract is then pumped over the immobilized cells for the fermentation stage.

Miso

Miso is made with either added rice or added barley (Figure 7). The carbohydrates are cooked for ~40 min and the soybeans are soaked and cooked at 115°C for

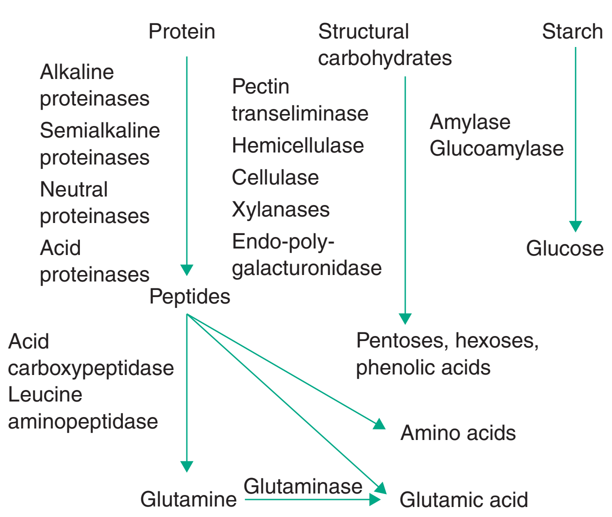

Figure 6 The fungal enzymes in the koji act on the three main components in the soybean : wheat mixture: the proteins, the structural carbohydrates, and starch. The amino acids and glutamic acid are important flavor and nutritive components, the pentoses, hexoses, and phenolic acids are important precursors for flavor compounds, the breakdown of the structural components eases the filtration of mash at the end of aging, and the glucose is an important precursor for acids, ethanol, and other flavoring compounds.

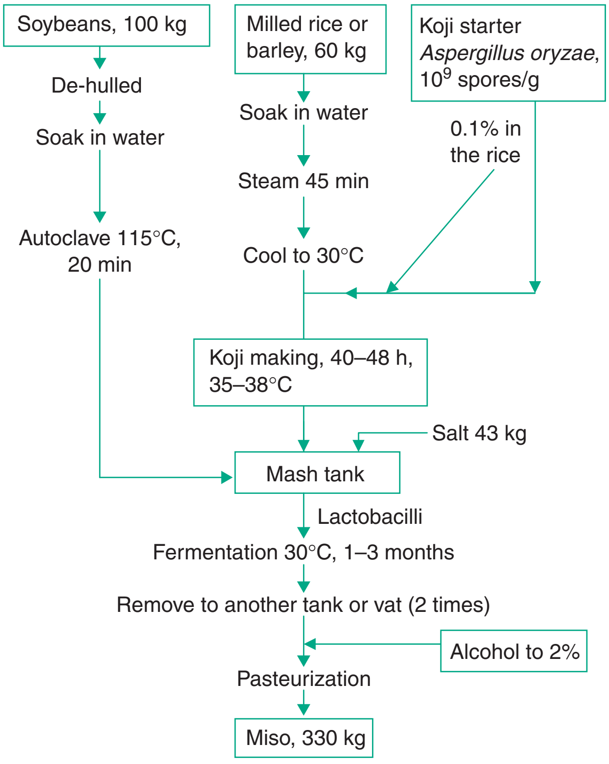

Figure 7 A flowchart for the production of miso. In this case the koji is prepared with the starch source alone and a slightly higher incubation temperature is used to promote amylase production over protease enzyme production. (Adapted from Yokotsuka T and Sasaki M (1998) Fermented protein foods in the Orient: *shoyu* and *miso* in Japan. In: Wood BJB (ed.) *Microbiology of Fermented Foods*, vol. 2, 2nd edn., pp. 351–415. London: Elsevier Applied Science.)

20 min. The koji mold, *A. oryzae*, is grown only on the rice or barley. It is inoculated and incubated at 35–38°C for 40–48 h to promote amylase instead of protease production. Salt is added immediately to prevent further mold growth and the salted rice or barley koji is mixed with the cooked soybeans. Lactic acid bacteria and yeast may be added. The mixture is packed in a tank and covered and incubated at ~30°C. During aging, it is moved from one tank to another to mix the contents and to introduce some oxygen to promote yeast growth. The aged miso is then blended, mashed, and pasteurized, and ~2% alcohol is added to prevent yeast growth.

Okara

The dry matter content of okara, the waste product from soymilk production, contains ~26% protein, 12% oil, and 52% complex carbohydrates such as hemicellulose, pectin, cellulose, etc. It is a waste product of growing significance, and the high insoluble dietary fiber content is a negative nutritional characteristic (*see* **Soybean**: Soymilk, Tofu, and Okara).

Fermentation of Okara

A traditional Chinese product is "meitauza" – produced with *A. elegans*. Acid protease enzyme from the mold releases ammonia and increases nonprotein nitrogen eightfold, while pH rises from ~5.5 to 7.5. A natto-like product has been produced with selected bacterial cultures.

Fermentations are usually tempeh-like, so okara cakes are inoculated with fungi and incubated. Using the tempeh fungus, *R. oligosporus*, and the koji fungus, *A. oryzae*, the nutritional quality of okara is improved because, on a dry matter basis, there are increases in protein digestibility (80–84%), free amino acids (0.02–0.41%), acid-soluble nitrogen compounds (0.15–0.84%), free sugars (12–18%), and inorganic phosphorus, and decreases in fiber content (56.6–49.5%). Phosphorus increase is due to hydrolysis of phytic acid that binds iron, making the iron unavailable in the diet. Added rice bran improves okara tempeh. The mold *Neurospora intermedia*, used to make Indonesian "oncom," a fermented groundnut presscake with an orange color, when grown on okara presscake, increases the protein content (22–27%), and decreases insoluble fiber, and fat content 15–9%. The texture of fried okara oncom resembles chicken.

Citric acid Citric acid is produced from okara with added 0.1% $(NH_4)_2SO_4$ and using solid-state fermentation with two mold cultures: *Aspergillus terreus* NCIM 653 and *A. niger* NRRL 330. *A. terreus* saccharifies the okara and noncellulolytic *A. niger* produces the citric acid. Maximum citric acid yields of 5.1 g citric acid per 100 g of dry solids, are obtained when *A. niger* and *A. terreus* are grown together.

Okara Fermentations for Nonfood Purposes

Usually solid-state fermentations are used. *B. subtilis* NB22, incubated at 25°C, produces iturin A, a cyclic heptapeptide of α-amino acids connected by long β-amino acids, that is effective against serious plant pathogenic fungi. Up to 11 g per kg dry-weight okara of iturin A has been produced. *B. subtilis* RB14 growing on okara produces surfactin, a lipopeptide consisting of iso-C_{15}-hydroxy carboxylic acid and a seven-member ring structure of amino acids, that inhibits fibrin clotting and lyses erythrocytes, sphaeroplasts, and protoplasts, and is a powerful biosurfactant able to lower water surface tension from 72 to 27 mN m^{-1}. Surfactin production as high as 2.0 g per kg wet weight was achieved during growth at 37°C. Fibrinolytic enzyme production by some *B. subtilis* strains was 2.5-fold higher when grown on okara compared with whole soybeans.

For *Penicillium simplicissimum* AK-40 okara was the best medium for the production of some novel compounds with insecticidal properties called okaramine A ($C_{32}H_{32}N_4O_3$) and B ($C_{33}H_{34}N_4O_5$), and another strain, ATCC 90288, produced the insecticidal agent, okaramine D.

Health Benefits of Fermented Soybean Products

Fermented soybeans are thought to have some beneficial effects on health. The benefits arise from the fiber components in the products, and from metabolically transformed components.

Tempeh

Tempeh made with *R. oligosporus* has high free radical scavenging activity, one-third of which comes from isoflavones released by fungal β-glucosidase from the glycosides, and two-thirds from the peptides. One of the antioxidants is 3-hydroxyanthranilic acid (HAA), when it is at high levels in cell culture, inhibits production of the dominant membrane lipid, but at low concentration it accelerates membrane lipid formation. Also HAA inhibits cell growth and induces apoptosis in a human hepatoma-derived cell line (HuH-7), suggesting it may have anticancer properties.

To study the antioxidative, anti-inflammatory, and antithrombotic properties of tempeh, male Wistar

rats were fed an aqueous tempeh extract for 7 days and then their femoral arteries were observed using a γ-camera. When free radicals were induced in the rats, the animals fed the tempeh extract had lower interleukin-1 α-plasma levels, and reduced plasma thromboxane B2 plasma levels, suggesting a protective effect against atherosclerosis. Okara-based tempeh, when fed to rats, increased levels of cholesterol and bile acid in the faeces and significantly lowered them in plasma while liver cholesterol levels were lower compared with controls.

Natto

The *B. subtilis* var. *natto* used to manufacture natto produces enzymes that break down enterotoxins produced by *Staphylococcus aureus*. Natto has positive effects on osteoporosis. Ovariectomy-induced bone loss in rats was used as the model and when fed natto containing added isoflavone (446–924 mg per kg isoflavone, including genestin, genistein, daidzin, and daidzein) and zinc along with added calcium, serious bone loss in the rats over a 3 month trial period was prevented. A crude antioxidant preparation called NTX from natto-fermented okara exerted an anti-inflammatory effect on the gastric mucosa better than α-tocopherol due to scavenging of the superoxide anion, and in the diet it repressed oedema when induced in rat foot pads by subcutaneous injection of croton oil. NTX also lowered levels of serum thiobarbituric acid-reactive substances, total cholesterol, low-density lipoprotein cholesterol, and triacylglycerol, as well as depressing atherosclerosis in rabbits. Natto intake also increases serum levels of vitamin K_2 (menaquinone-7) in humans.

Miso

A powerful antioxidant isolated from *A. oryzae* fermented soybean is 6-hydroxydaidzein in addition to 8-hydroxydaidzein and 8-hydroxygenistein. However, it was only produced when the soybeans were used to make the koji, not when rice or barley were used. It helps prevent oxidative deterioration of miso. Protein and fiber components in okara koji made with *A. oryzae* affect lipid metabolism in rats. Lower cholesterol levels in plasma and liver and lower triglyceride levels were found in rats fed a diet containing 50% okara protein enriched with *A. oryzae* compared with a casein-based control diet. The antioxidants in *A. oryzae* fermented okara are γ- and δ-tocopherol, the isoflavones genistin, daidzein, genistein, and HAA.

The antimammary cancer effects of miso were tested in combination with tamoxifen in rats. The tamoxifen was implanted subcutaneously and the miso fed at 10% of the diet. Mammary cancer was induced and while both the miso group and the tamoxifen group showed reduced cancer rates, the two together showed a synergistic effect. The incidence of tumors in the control group, the miso fed group, the tamoxifen implanted group, and the miso + tamoxifen group were 91%, 77%, 68%, and 10%, respectively.

Iron absorption in children can be improved by feeding fermented soybean. Microbial hydrolysis of the phytate reduces its iron-binding capacity. When fed to 437 children in China for 6 months, the incidence of iron deficiency dropped from 21.7% to 1.25% and the iron absorption rate was 21.8% in the children given fermented soy and only 14.2% on the control diet.

Soymilk, Tofu, and Okara

D K O'Toole, City University of Hong Kong, Hong Kong, People's Republic of China

Soybeans have been grown and consumed in China for over 4000 years, and about 2000 years ago the technology for extracting soymilk was developed. Following this, three main products are now produced using soymilk, tofu, yuba, and okara, the main waste product. With the increasing popularity of soymilk and soymilk-based products, okara is becoming an increasing disposal problem. Many approaches to using okara are being researched, including fermentation methods for food products or industrial products, and its use as a food additive. The production of tofu involves the use of the traditional calcium or magnesium salts, or the modern use of glucono-delta-lactone from which acid is produced to coagulate soymilk. Growth conditions, soybean variety, and storage conditions influence soymilk characteristics that vary considerably and affect tofu production and yield, as well as characteristics. Yuba is the thin film of protein that forms on hot soymilk when heated openly. Soybeans contain antinutritional factors that must be destroyed by heating and the soymilk develops a "beany" taste that many Westerners find distasteful. This flavor is due to the action of an enzyme that oxidizes the long-chain unsaturated fatty acids.

Introduction

Soybeans, first cultivated in the Yellow River Valley in China ~5000 years ago and on record from ~sixteenth to eleventh century BC, contain about 34% protein, 20% oil, and about 30% carbohydrate that is comprised of a soluble and an insoluble fraction. The soluble carbohydrate fraction, about 10% of the bean, is a mixture of sucrose (5%), raffinose (1%), and stachyose (4%), and the insoluble fraction consists of pectin (30% of insoluble carbohydrate), hemicellulose (50%), and cellulose (20%), and there is less than 1% starch. Soy hemicellulose consists mainly of arabinogalactan. About 12% of the protein is water soluble. In the beginning soybeans were cooked and eaten but then in the West Han Dynasty, ~2000 years ago, Liu An, who dates from ~164 BC, is said to have invented tofu that required the extraction of soymilk from the beans (*see* **Milling and Baking, History**). A major problem with soybeans is that they contain a trypsin inhibitor, an antinutritional agent that prevents the intestinal digestive enzymes from breaking down proteins, and that must be destroyed by heating for a few minutes (Figure 1) to obtain maximum nutritional value (*see* **Nutrition**: Beriberi, A Deficiency Related To Grains).

Because soybeans have a high protein content, they, and products derived from them, are seen as animal protein substitutes. In their raw state the concentration of nutrients is high, by comparison with beef, eggs, and milk (Table 1), but when prepared for consumption soybean products have significantly lower nutrient concentrations (Table 2). Apart from the fermented products obtained from soybeans (*see* **Nutrition**: Guidelines for Grain-Based Foods and **Soybean**: Soy-Based Fermented Foods), there are four main products and by-products: soymilk, tofu, yuba, and okara.

Soymilk Production

The traditional soymilk production method involves soaking the beans to rehydrate them, rinsing,

resuspension in water and grinding of the beans, followed by filtration to separate the soymilk and fibrous residue. The Japanese developed a slight variation in the traditional Chinese method (Figure 2) that improved soymilk yield and improved filtration characteristics but at the cost of a tendency to burn the slurry and the need to use mechanical means to filter the hot mixture, as well as increased energy costs. Usually the ratio of water to beans is in the range from 8 : 1 to 10 : 1. About 70% of bean solids, 80% of bean protein, and 89% of the oil end up in the soymilk. The residue left is known by a variety of names: okara, draff, tofukasu, soy pulp, tofu residue, tofu cake, dou zha (Chinese), bejee (Korean), and tempeh gembus (Indonesian).

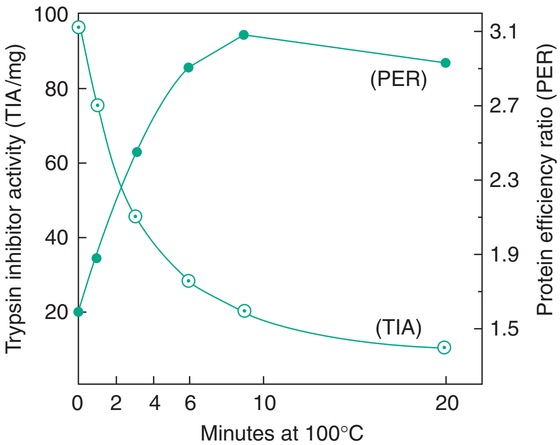

Figure 1 The effect of heating time on the protein efficiency ratio (PER) and its relationship to the trypsin inhibitor activity (TIA) in soybean. As trypsin activity drops, the digestion of the protein improves as shown by increased PER.

During soymilk production distinctive flavors develop that are variously described as "beany," "painty," "rancid," and "bitter." People from East Asia are used to the flavor but those in other places are generally not used to it. The flavor is due to the action of a native soybean enzyme, lipoxygenase (*see* **Enzyme Activities**). The enzyme reacts with the unsaturated fatty acids in the oil (linoleic acid, etc.) in the presence of water, and oxygen, by a process called autoxidation resulting in hydroperoxides (Figure 3) that are then broken down to aldehydes and ketones with strong odors and flavors, e.g., hexanal that has a flavor threshold of less than 1 mg kg^{-1}. Normally, in the whole undamaged bean, the oil and the enzyme do not come into contact but, when the beans are ground, contact with the necessary elements of the reaction occurs so that the reaction can proceed. As heat

[b] Concentration of components in soymilk depends on the soybean : water ratio used to make the slurry.
[c] Values from a Japanese paper, tonyu is the Japanese term for soymilk.

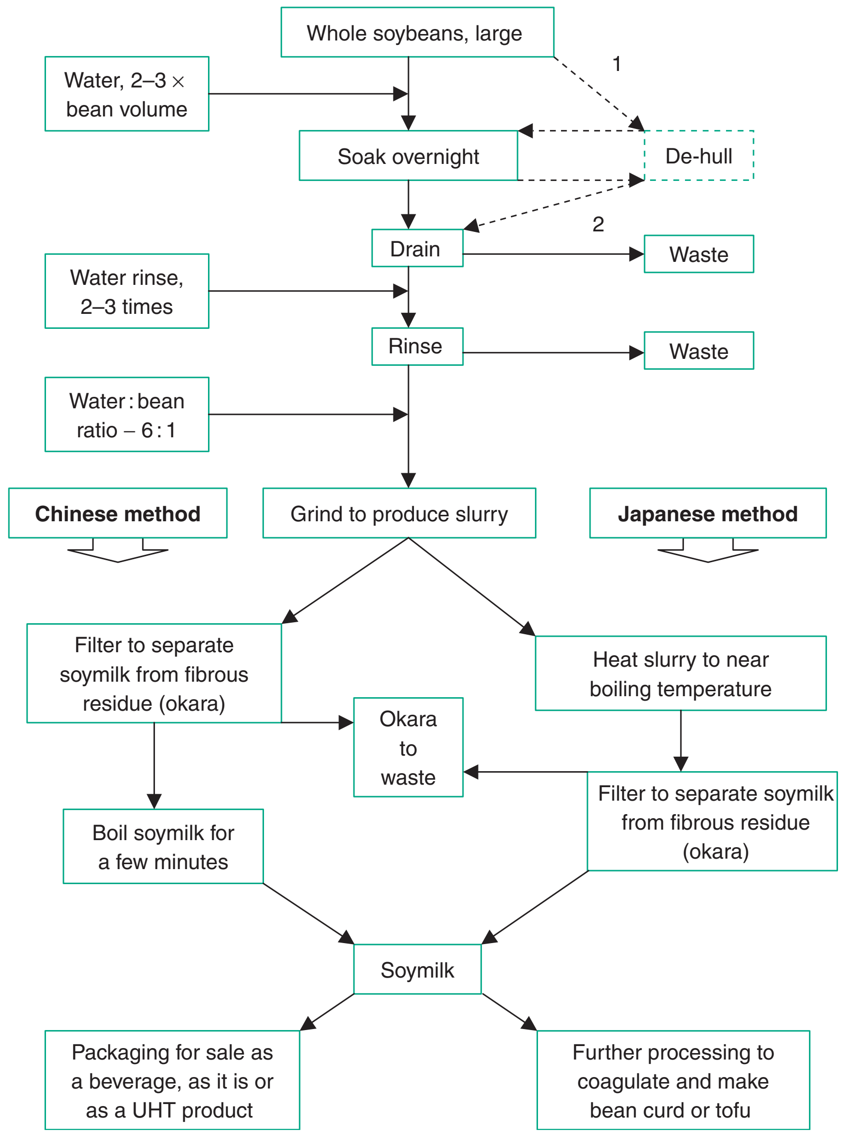

Figure 2 A schematic diagram of the production of soymilk by the Chinese and the Japanese methods. Soybeans may be de-hulled before they are put in to soak or the hulls may be removed at the end of the soaking stage, or the hulls may not be removed at all. Okara is a major by-product from the process.

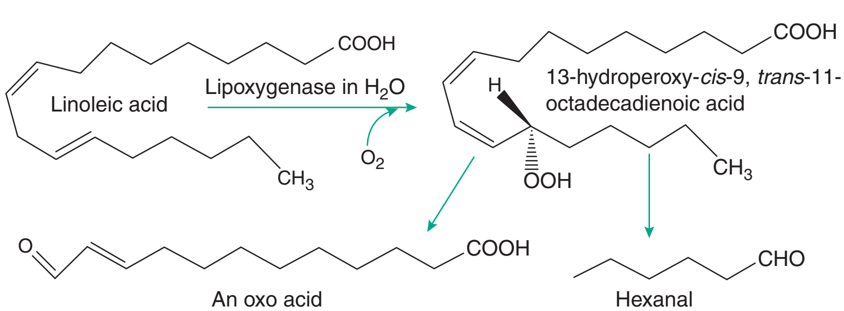

Figure 3 The lipoxygenase enzyme is responsible for the “beany” flavor commonly noted in soymilk. The reaction catalyzed by the enzyme involves water, the unsaturated oil, and oxygen and the end-product hexanal is one of the compounds responsible for the beany flavor.

destroys the enzyme, possible processes to prevent bean flavor development include heating the dry beans, grinding the beans in hot water, and blanching the beans, but these processes render some soy protein insoluble, may introduce cooked flavor, and affect soy protein function. However, lipoxygenase is of value for the organoleptic qualities of tofu and soymilk, because tofu made with lipoxygenase-deficient soybeans lacks "mouthfulness" or richness, and soymilk made with similar soybeans results in soymilk with a darker yellow color.

Modern continuous production systems try to balance these factors. Recognized processes include:

- *Cornell method*. Soybeans are de-hulled and ground in a hot grinder with hot water at 80–100°C. The slurry is then boiled in a steam-jacketed kettle and constantly stirred for 10 min, followed by centrifugation or filtering to remove okara.
- *Illinois method*. Soybeans are de-hulled and either presoaked and placed in boiling water for 10 min, or placed dry in hot water for 20 min, then drained and ground in sufficient cold water to make a slurry with 12% solids that is then heated to 93.3°C and homogenized. Added sodium bicarbonate (0.25–0.5%) in the early stage may be used to hasten enzyme inactivation and has to be neutralized after homogenization. The resulting product, while bland in flavor, unfortunately has a chalky feel in the mouth. Soybean hulls are the only solid waste product.
- *Rapid hydration hydrothermal cooking method*. Soybeans are ground into flour, mixed with hot water, okara removed by centrifugation and soymilk pumped to a steam injection head where live steam is injected to increase temperature instantly (UHT conditions, 154°C for 30 s), and the soymilk is held in a holding tube to deactivate trypsin inhibitors. Okara waste results (e.g., the Tetra Alwin^{TM} Soy system).
- *Full fat soy flake method*. The process begins with a product called MicroSoy Flakes made by the MyCal group of Iowa, USA, from de-hulled soybeans.
- *Commercial integrated production systems*. Some of these systems are designed to be continuous and incorporate steps to minimize "beany" flavor development, such as procedures to minimize incorporation of oxygen that reacts with lipoxygenase.

Large soymilk manufacturers may include a deodorization step at the conclusion of soymilk extraction. The hot soymilk is injected into a chamber under strong vacuum in which volatile off-flavors, such as sulfur flavors, short chain fatty acids and vinyl or sterol compounds, and air in the soymilk, are vaporized and stripped out. The soymilk is also rapidly cooled as it expands into chamber.

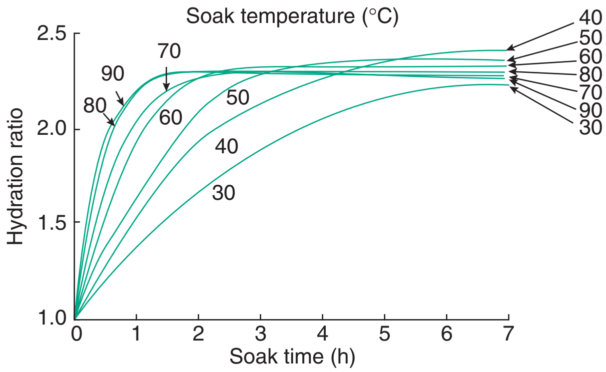

Figure 4 The time to maximum water uptake (hydration) by soybeans depends on the temperature of the soak water.

Whether or not the soybeans should be de-hulled before processing is debatable, because the process can damage the cotyledon thus releasing the enzyme but some benefits include elimination of a "green or raw" flavor, and reduced soaking time. Soaking time to full soybean hydration is fastest at 80–90°C and much slower at room temperature (Figure 4). During maceration to produce the slurry, the seedcoat does not behave the same way as the cotyledon cells.

Tofu

Tofu resembles a soft white cheese and can be defined as "a water extracted and salt- or acid-coagulated soy protein gel with water, soy lipids, and other constituents trapped on its network" that was developed in China and spread through East Asia (*see* **Nutrition**: Soy-Based Foods). It was introduced into Western cuisine less than 100 years ago. The manufacture of tofu with consistent quality and yield is difficult as many things can affect the outcome.

In the production of tofu, various coagulants are used to solidify the soymilk. They include magnesium chloride, calcium sulfate, and glucono-delta-lactone. The general process is outlined in Figure 5. Factors affecting the quality and yield of tofu include:

- *Size, shape, and color of hilum and cotyledon of the soybean*. Light colors are favored and although a large size, 200 mg per seed or larger, is a traditional Japanese requirement, there seems to be no scientific basis for it.
- *Total protein and the 11S–7S protein ratio* (*see* **Soybean**: Soy Concentrates and Isolates). Japanese manufacturers prefer soybeans containing 13% moisture with a 38% or greater protein content. The 7S fraction is β-conglycinin and the 11S fraction is glycinin and the concentrations and ratio

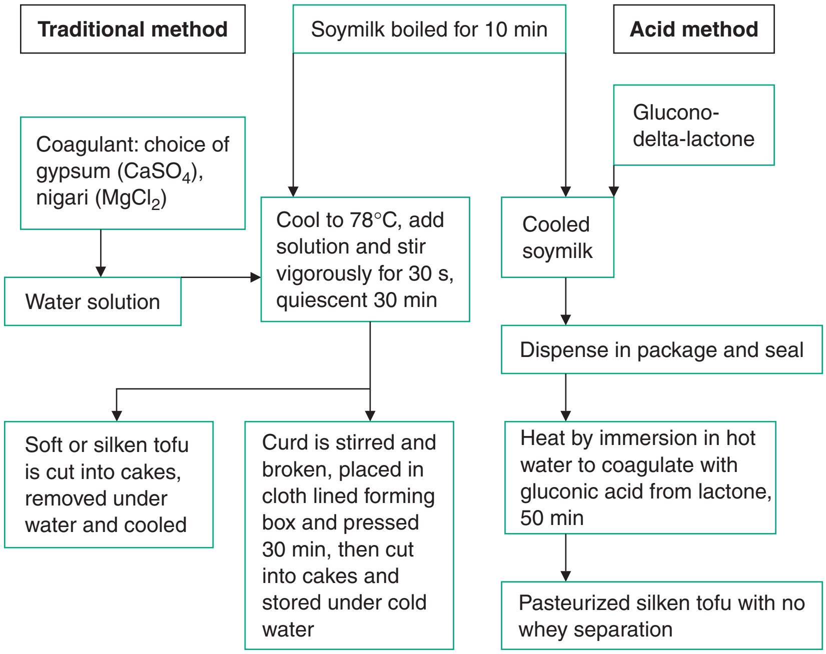

Figure 5 A schematic diagram of the production of tofu. Traditionally calcium and magnesium salts have been used as coagulants but a more recent innovation is the use of an acid coagulant, gluconon-delta lactone that slowly hydrolyzes to gluconic acid to cause the coagulation of the proteins. The final product is manipulated in various ways to form the final shape and form of the tofu being produced.

Table 3 Soybean cultivars vary in their protein content and the ratio between the protein fractions 11S and 7S and they have an impact on the tofu yield and tofu firmness

Cultivar	*Soybean (g per 100 g soybeans)*			*11S/7S ratio in protein*	*Tofu firmness (N)*
	Moisture	*Protein*	*Tofu yield*		
Vintron-81	9.67	49.6	293	3.33	10.02
S-20F8	9.40	49.1	269	3.57	9.91
HP-204	9.06	48.5	320	3.10	8.53
IA-2034	9.66	47.9	322	1.85	8.19
Steyer	9.71	47.9	314	2.40	7.97
IA-2020	9.19	45.9	343	2.24	7.84
S-2020	9.04	42.9	290	2.05	6.93

of these vary with seed cultivar (Table 3). The 11S fraction controls hardness, brittleness, and gumminess of resulting tofu, and the 7S fraction requires more calcium or magnesium for coagulation. Hence, the ratio of these two proteins in a soymilk influences the process and product characteristics. The 11S fraction, the α' polypeptide of 7S, and the basic polypeptide of 11S seem to each affect tofu yield but they are not related to tofu firmness. However, there is a relationship between tofu firmness and the 11S fraction, the 7S fraction, and their ratio. The effect of the 11S : 7S ratio may be modified by the processing conditions.

- When calcium sulfate is used for coagulation, the concentration of the salt for optimum tofu quality declines from ~0.8% (w/w) to ~0.4% as the concentration of protein in the soybeans rises from 31% to 38%. The recommended concentration is 0.02–0.04 mol, but in practice experienced tofu makers know if the amount is correct by whey color and curd texture. If concentration is just right, the whey is transparent with amber or pale yellow color and sweet taste, and if too much coagulating agent is added the whey is slightly bitter and the curd has a coarse texture.
- As grinding temperature rises from 2°C to 50°C, the firmness of resulting tofu declines. This is due to the activity of the lipoxygenase enzyme whose reaction by-products, the peroxides, oxidize the –SH groups on the soybean protein being released during the grinding and so reduce protein cross-linking.

- The percentage of total solids in soymilk is related to the water : soybean ratio. The water value used is the total amount of water absorbed by the dry beans plus the final addition of water for grinding plus any rinse waters from the residual okara added back to the slurry. Maximum protein yields are obtained at a ratio of 10 : 1, water : soybean, but at a ratio of 9 : 1 pressed tofu has the lowest fresh yield and cohesiveness, and highest brittleness and hardness.
- The coagulation temperature depends on type and concentration of coagulant, how the coagulant is added in, and tofu type to be produced. Generally, as the temperature used is increased (50–90°C) tofu yield decreases, but at the lower temperatures tofu is soft and at higher temperatures tofu is hard and uneven. Consequently, the optimum temperature range is 70–80°C.
- If the soymilk is stirred with added coagulant, the resulting tofu has a hard curd and a low fresh yield is obtained. High-speed stirring favors hard curd production and low-speed stirring for a short time favors softer curds.
- Although soybean variety affects tofu qualities and yield, the growing season for the production of the soybeans has a major impact on tofu texture, due to the effect of environmental growth conditions on the 11S : 7S ratio in the protein.
- When soybeans are stored under adverse conditions of high temperature and relative humidity, the tofu yield decreases and tofu hardness increases (Table 4).

During the production of tofu, additives are sometimes included to change the tofu characteristics or to improve textural characteristics. Added blood in Japan, algal cells (*Chlorella* sp.) in Korea, and chitosan have also been used to improve tofu texture. Commercial transglutaminase or glucose at a low level, when added at $\sim 5\ \mathrm{mg\,l^{-1}}$ to soymilk to make glucono delta lactone tofu, suppresses retort-induced water release during sterilization at 115°C for 20 min.

Table 4 The affect of storage of soybeans under adverse conditions, at 85% relative humidity and 30°C, on phytate concentration in the soybeans and the yield of tofu and the brittleness and hardness of the tofu measured in grams

Months of storage	*Phytate (g per 100 g of soybeans)*	*Tofu yield*	*Brittleness (g)*	*Hardness (g)*
0	1.33	512	1020	2090
1	1.21	505	1033	2182
2	1.18	481	923	2465
3	1.16	421	873	2704
4	1.10	389	920	3080
5	1.06	362	945	3278
6	1.05	233	>5000	>5000

Tofu is classified into soft (silken), firm, and extra firm varieties. Subsequent processing results in a range of products. Silken tofu contains 88–90% water and 6% protein and is made with soymilk containing 10–12% solids. The curds, when broken and pressed, result in firm and extra firm tofus. The firmness makes it easier to handle the small curd blocks so they keep their shape during slicing and cooking by deep frying or pan frying.

Products, depending on subsequent handling, include plain tofu, frozen tofu (a 1000–1500 year old Chinese tradition), dried-frozen tofu, deep-fried tofu, grilled tofu, and fermented tofu (*see* **Soybean**: Soy-Based Fermented Foods). Frozen tofu has an interesting characteristic. On freezing the tofu solids congeal into a firm network, and on thawing the water is released from the tofu block leaving behind a product with a sponge-like texture that is tough and chewy but it absorbs flavors easily. The thawed tofu, when dried (dried-frozen tofu), keeps well (up to 12 months), is easily handled and stored, and is a highly concentrated source of protein and energy.

Soymilk- and Tofu-Based Foods

Although the name "soymilk" is commonly used, there is some resistance to the use of "milk" in the name, because milk has been more commonly associated with the bovine-derived product. Consequently, it is sometimes named "soy beverage." Many modern products have been referred as second-generation soy foods because they are modern inventions as opposed to the traditional products above, but a clear-cut definition of these products is difficult. Broadly, they can be placed into three categories: dairy analogs, meat analogs, and tofu-based foods.

The soymilk-based dairy analogs are foods basically the same as dairy products, but soymilk and soy constituents are used instead of milk and milk constituents. Consequently, the soy-based analogs include frozen soy deserts such as soy ice cream and frozen soy yogurt. Generally, dairy ice cream is made from a mixture of ingredients that include water, high fructose corn sweetener (or sucrose), fruits, vegetable gums, salt, and colorant but in soy ice cream the dairy constituents are replaced with soy oil, tofu, isolated soy protein, and soy lecithin. Frozen soy yogurt is basically made from a mix similar to that found in soy ice cream except that it is cultured with the two yogurt lactic acid bacteria (*see* **Soybean**: Soy-Based Fermented Foods) and frozen and whipped as

for normal ice cream. The product resembles a regular soft serve frozen product.

Attempts to make fermented dairy analogs such as cheese and yogurt from pure soymilk have generally failed for a variety of reasons. They include that the soy protein molecules are larger than milk proteins and have different functional groups and characteristics; the fat to protein ratio in tofu is lower than in cheese, 0.55 : 1 versus 1.1 : 1, that results in a hard product; sugars in soymilk do not support growth of dairy bacterial cultures; and acid production by the usual dairy microorganisms in soymilk is variable. Consequently, processes used for dairy products manufacture cannot be easily adapted to soymilk. Products similar to cheese can be made but it requires addition of dairy constituents and enzymes to obtain products similar to dairy cheeses.

The idea of making meat analogs from soybean dates from the 1950s. There are two basic processes for manufacturing meat burger-like products, namely fiber spinning and thermoplastic extrusion. Fiber spinning is used to make fibrous meat-like products that are used in the production of "meat" pies, casseroles, seasoned vegetables, and sandwich fillings. Flavors such as bacon flavor can be added to the product. Thermoplastic extrusion is used to make textured vegetable protein (TVP) that can be formed into continuous slabs for eventual cutting into desired shapes such as burger shapes. Various flavors and spices can be added to make the product flavorful. These meat analogs can be marketed as low fat and cholesterol free as well as being vegetarian.

Tofu is very versatile and can be used to make very many Western style foods. Tofu has been used to make cheesecake, dips, pies, cream cheese, mayonnaise, Italian meatballs, and almost any Western style food.

Okara

About 1.1 kg of fresh okara is produced from every kg of soybeans processed for soymilk. Okara contains ~30% of the whole soybean solids, 20% of the bean protein, and 11% of the oil. Huge quantities of okara are produced, e.g., in Japan ~700 000 ton (t) of okara were produced from the tofu production industry in 1986, and its disposal is a significant problem. The okara is used as an animal food, is dumped in landfills, is used as a fertilizer, and, in Japan, most is burnt. It has been used as a base for a low cost artificial food for silkworms for the first to the third larval instar stages of growth. Research is ongoing to devise uses for okara including the development of other processed human foods. When dry okara is mixed with rice powder in the ratio of 25 : 75 to prepare a sauce-like product using a soy sauce manufacturing technique (*see* **Soybean**: Soy-Based Fermented Foods), the resulting product has an excellent flavor with a light and bright color, but total amino acids and glutamic acid are lower than found with a 1 : 1 mixture of defatted soybean meal and wheat. Okara is not suitable for ethanol production.

Preservation of Okara

Due to its high water activity and microbial contamination, okara can putrefy quickly so if it is not used immediately it must be preserved. It is desirable that during preservation the okara should retain its white color and ability to easily absorb water. For short-term storage a lactic acid fermentation will suffice, but drying is the preferred solution.

Fresh okara tends to be lumpy so there are homogeneity problems during drying. Successful drying systems depend on the initial moisture content of the okara. Dehydration methods include addition of water-absorbing synthetic polymers in various forms to the okara; the use of a patented process involving a pneumatic conveying drier and a pulverizer; or a pneumatic drying system with hot air (208–254°C) at a low velocity ($192\ \mathrm{m\ min^{-1}}$) in a large drying tower. Other drying systems include a vibro-fluidized bed under vacuum, and drying in pellet form ($3\ \mathrm{mm} \times 10\ \mathrm{mm}$) in hot air. Sterilized wet okara can be produced continuously by finely dividing it and feeding it into a scraper-type heat exchanger at not less than 120°C followed by cooling, filling, and sealing aseptically in a suitable container.

Okara Composition

The main components of okara are ruptured cotyledon cells and the seedcoat. The proximate composition of the wet okara depends on the water extraction efficiency from the slurry phase and soybean cultivar from which it is extracted, amongst other factors. Okara has a pH of ~6.7, and on a dry-weight basis its proximate composition is 27% protein, 10% crude fat/oil, and 14% soluble fiber, 42% insoluble fiber, and 3% ash. The proximate insoluble fiber content is 12% hemicellulose, 5.5% cellulose, 11.5% lignin, and 0.2% phytic acid. Other nutritionally important compounds include vitamins: thiamine, riboflavin and nicotinic acid, as well as calcium, phosphate, zinc, iron, copper, and magnesium (Table 5). The phytic acid (inositol hexa-phosphate), when consumed in large quantities in the diet, reduces calcium balance and metal ion availability, and the zinc has low bioavailability. Soluble carbohydrates include sucrose as well as raffinose and stachyose that cause meteorism (flatulence) (Table 6).

Table 5 The proximate composition, mineral analysis, and vitamin analysis on a dry matter basis of okara prepared from three cultivars of soybeans

Soybean cultivar	*Proximate composition (g per 100 g)*							*Minerals and vitamins (mg per 100 g)*

Fractionation of Okara

Okara, as a waste product, is a cheap resource, so to add value to it various components can be isolated in fractionating steps to produce high-value products such as proteins and carbohydrates that can be used as food additives.

Protein The protein in okara is of better quality than that from other soy products, e.g., the protein efficiency ratio of okara is 2.71 compared with 2.11 for soymilk (*see* **Nutrition**: Guidelines for Grain-Based Foods), but the ratio of essential amino acids to total amino acids is similar to tofu and soymilk. Protein extracted from heat-treated and nonheat-treated okara differs, the latter contains the same basic 7S globulin found in soybeans, unlike the former. Okara protein isolate is similar to commercial soy isolate in having comparable emulsifying, water and fat binding, and foaming properties.

Pepsin digests of proteins lower hypertension and blood pressure because they contain peptides that inhibit the angiotensin I-converting enzyme (ACE) that converts angiotensin I to angiotensin II, a substance that constricts arteries leading to hypertension and raised blood pressure. The peptides have IC_{50} (concentration at which 50% inhibition is found) values between 14 and 53 μmol.

Okara fiber component Cellulose concentration is higher in the seedcoat than in the cotyledon but hemicellulose is lower in the seedcoat and higher in the cotyledon, and although galactan hemicellulose is present in the two seed components, araban hemicellulose is present in cotyledon and pentosan hemicellulose in seedcoat. Arabinogalactan hemicellulose is the main constituent in the alkaline extract (24% KOH) from okara.

Demethylation of okara hemicellulose results in a low-viscosity water-soluble carbohydrate that can be used to stabilize soluble proteins under acid conditions, e.g., in acidified milk beverages.

The hemicellulose content of okara can be fractionated into hot-water-soluble, normal-soluble, and alkali-soluble hemicellulose at ratios of 5 : 19 : 4 after soaking at 30°C overnight. Hot water extraction from okara has been done by hydrolyzing in an autoclave at pH 4.5 in two volumes of water with or without a chelator (hexametaphosphate or ethylene diamine tetra-acetic acid (EDTA)). The extracted polysaccharides, molecular weight of $\geq 10^5$, have emulsification properties influenced by the amount of bound protein. The use of sodium hexametaphosphate results in protein-free pectic polysaccharides with characteristics similar to commercial pectic polysaccharides products.

Table 6 Carbohydrate (not fiber) contents on a dry matter basis, of okara from three cultivars of soybeans (g per 100 g)

Soybean cultivar	*Monosaccharides (unspecified)*	*Oligosaccharides*			*Starch*
		Stachyose	*Raffinose*	*Sucrose*	
Edgar	0.7	1.4	0.3	2.3	0.59
Hutton	0.6	0.9	0.3	1.3	0.68
Prima	0.7	0.9	0.4	1.8	0.79

The monosaccharides units in the polysaccharides in the insoluble fiber components, when enzymatically digested, include galacturonic acid, glucose, xylose, arabinose, and galactose.

Human Consumption

The dietary fiber content of okara is greater than 50%, so its energy content is only half that of wheat flour. Okara alone has some antinutritional qualities; however, fermented okara may have definite dietary advantages. It can act as a suitable replacement for digestible food in a food prepared to reduce calorie intake, when consumed, it can reduce cholesterol levels in the blood stream, and as a food that contains antioxidant activity, similar to vitamin E, it can reduce the level of free radicals in the body.

Nonfermented products Haarman and Reimer Corp. in the USA developed an okara-based snack bar, and the Japanese National Food Research Institute patented a process for converting okara to a textured soybean product. Biscuits fortified with 60% okara to give protein and dietary fiber contents of 8.72% and 5.98%, respectively, are acceptable to consumers. The Japanese patented a process to produce okara coated with shortening for use as a wheat substitute for making cakes acceptable to consumers. A nougat candy based on peanut, glucose, hydrogenated oil, sugar, and natural essences with added okara has been developed in Argentina. The candy contains 18.3% okara and 27.4% peanut. Acceptable corn tortillas can be made with 10% added okara, and the tortillas have increased lysine and tryptophan levels, amino acids that are nutritionally limited in corn.

Fermented products A traditional Chinese product is meitauza that is produced with okara using the fungus *Actinomucor elegans* in a solid-state fermentation, and another is pickled okara. However, much recent work has to do with using some traditional fungi and bacteria to produce nutritious and flavorsome okara-based products.

Okara-based natto has been produced using selected strains of *Bacillus natto*. Indonesian ontjom (oncom), an orange colored product, has been prepared from okara using the fungus *Neurospora intermedia*. The resulting product has no soybean flavor, smooth mouth feel, and, when fried, the texture of okara ontjom resembles chicken (*see* **Soybean**: Soy-Based Fermented Foods).

The tempeh fungus, *Rhizopus oligosporus*, and the soy sauce fungus, *Aspergillus oryzae*, improve protein digestibility, and availability of nutrients in the fermented okara along with its antioxidant activities.

In rats fed with a diet containing 50% okara protein enriched with okara koji fermented with *A. oryzae*, plasma- and liver-cholesterol levels and triglycerides (compared with a casein-based control diet) are lower. The protein and fiber components in okara koji made with *A. oryzae* and *R. oligosporus* affect lipid metabolism in rats. Plasma levels of cholesterol and bile acid are significantly lower in okara tempeh fed animals apparently due to cholesterol and bile acid being more strongly bound to okara fiber than cellulose fiber and so they are excreted in the faeces. Dietary fiber, particularly that from the soybean, may be effective in modifying colonic conditions in a positive way (*see* **Nutrition**: Guidelines for Grain-Based Foods). Rats fed with fermented okara absorb more iron than those fed with unfermented okara, possibly due to reduced levels of phytic acid.

Fermented okara, compared with unfermented okara, contains more of an antioxidant, called NTX, that has an anti-inflammatory effect on gastric injury in the gastric mucosa. In *in vitro* tests NTX scavenges the superoxide anion, a process that also occurs *in vivo*. When foot pad edema is induced in rats by subcutaneous injection of croton oil, NTX fed rats exhibit repressed edema but rats fed with a control diet or vitamin E show no repression of edema. The antioxidants in *A. oryzae* fermented okara seem to be γ-and δ-tocopherol, the isoflavones genistin, daidzein, genistein, and 3-hydroxyanthranilic acid. In vitamin-E-deficient rats fed with okara supplemented with the oxidized oil, the body weight gain was lower and plasma peroxidase activities lower than in those fed with fermented okara suggesting that the antioxidants in the fermented okara scavenged lipid peroxides *in vivo*.

Fermentation for Nonfood Products

Some unusual and possibly useful chemicals, new and previously described, including iturin A and surfactin,

have been produced by some microorganisms growing on okara only but not other substrates in a solid-state fermentation (*see* **Soybean**: Soy-Based Fermented Foods). When growing on okara, *Penicillium brasilianum* Batista JV-379 produces two compounds, namely brasiliamide A and B, that cause convulsive responses in silkworms. Strains of the fungus *P. simplicissimum* produce okaramines, some with insecticidal properties. In addition, they produce a unique oleanane triterpene, and another species of *Penicillium* produces two new dihydroquinolinones, one toxic for the classic toxin indicator *Artemia salina* at an LC_{50} value of $20\,\mu g\,ml^{-1}$.

Other Products

The Japanese have patented a process in which okara is used to make a reinforced ceramic via the pozzolanic reaction. Fly ash (50–70%), clays (10–30%), and okara (10–20%) along with $Ca(OH)_2$ (10–30%) are mixed and heated in an inert gas to 1300–1500°C. The carbonized okara reacts with SiO_2 to form silicon carbide that strengthens the ceramic product.

Yuba

This product is made in Japan from soymilk. The soymilk is placed in a wide, open pan and brought to and held at a temperature close to boiling, the ideal temperature being 82 ± 2°C. Over time a slowly thickening film forms that can eventually be removed with two sticks. The film is placed on a wire mesh shelf to dry out. From 10 to 20 sheets may be produced from one batch of soymilk. It has a very high protein content and is highly digestible and nutritious (Table 2). It is highly perishable and is best eaten fresh but it is also sold in dried or semi-dried forms.

The yield and characteristics of yuba are affected by 11S and 7S proteins in the soymilk. Yuba made with soymilk containing 11S proteins is smooth, opaque, and strong, but that made with 7S soymilk is translucent, full of creases, and weaker by comparison (*see* **Soybean**: Soy Concentrates and Isolates). The pH of the soymilk is important. The normal pH of soymilk is ~6.7 but if the pH is below 6.2 the film will not form, and if the pH is 9 the yield and protein incorporation are at a maximum. Generally, a pH of 7–8 is recommended.

Detection of GM Soybean

As genetically modified soybeans are of concern, detection of genetically modified soybeans, e.g., Roundup Ready beans, in a batch is of interest. Using a Polymerase Chain Reaction process the *Agrobacterium* derived enzyme, 5-enol-pyruvyl-shikimate-3-phosphate synase gene used in the modification process, can be detected at the level of one modified soybean in 5000 unmodified seeds.

STARCH

Contents

Uses of Native Starch

J W Lawton, National Centre for Agricultural Utilization Research, USDA, Peoria, IL, USA

Published by Elsevier Ltd.

Introduction

Foods high in starch have always been an important part of the human diet. Traditionally, these foods high in starch have found their way into either human or animal food. Due to the abundance of these starchy natural materials, it is not surprising that applications other than its caloric value have been found for starch. Early in human history, starch was used to coat papyrus and the Romans documented the production of paste from white flour and vinegar. The variation found in the different sources of starch gives it great versatility in the types of uses. Starch can contribute to adhesion, viscosity, film forming, binding, and

moisture retention. Starch is an attractive industrial material because of its abundant supply, low cost, renewability, and ease of modification. Commercially available starches are mostly isolated from either cereals (corn and wheat), and from tubers and roots (potato and cassava). Of the total world production of starch, 83% comes from corn (Figure 1). In the US only ~2% of starch comes from sources other than corn. In the 2001 crop year, it is estimated that total cornstarch use, not counting cornstarch used for fuel ethanol and sweeteners, will be 250 million bushels. Using an average of 14.5 kg of cornstarch per bushel, estimated total use of cornstarch is ~3.6 billion kg in 2001. Smaller amounts of rice, sago, arrowroot, and pea starch are also available in commercial quantities. Of the wet-milled starch produced in the US, ~54% goes to sweeteners, 27% goes to manufacture of fuel alcohol, and 19% is used as starch. The largest user of starch is the paper industry, which accounts for 61% of the cornstarch uses. Food uses account for another 15%; other nonfood uses, after paper, account for the final 14% of manufactured cornstarch.

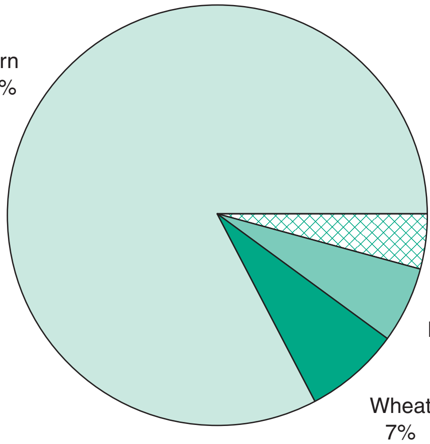

Figure 1 World production of starch.

Composition and Properties

Starch is deposited in the plastid of higher plants in the form of granules. The size and shape of these granules varies with botanical source (Table 1). The density of these granules is ~1.5 g cm^{-1}. The granules are comprised of two polymers of D-glucose that are amylose and amylopectin. Amylose is a lightly branched polymer, with molecular weights varying from 10^5 to 10^6, depending on the botanical source. Amylopectin is a highly branched polymer and its molecular weight ranges from 10^7 to 10^8. The ratio of amylose to amylopectin varies with the source. Most starches contain between 17–27% amylose and 72–82% amylopectin. Some cultivars have been found that contain starch with no amylose and others have been found that contain up to 70% amylose. Native starch granules are partially crystalline with the amount of crystallinity depending on its botanical source. Amylopectin is the polymer that provides the partial crystallinity of starch, whereas amylose is completely amorphous. The native crystalline structure of amylopectin consists of parallel stranded double helices. Native starch granules also contain small amounts of proteins, lipids, and minerals. Generally, the amounts of these minor constituents of starch make up less than 2% of the granule for cereal starches and less than 1% for tuber and root starches.

Gelatinization is the process of disrupting the molecular structure within the starch granule as it is heated in the presence of water. During the gelatinization process, the viscosity is increased by the granules absorbing water and swelling. Pasting is the

consequence of further heating after gelatinization. Additional heating causes the granules to become distorted, soluble starch is released into the solution, and eventually total disruption of the granules occurs. Many applications of starch rely on the rheological and textural properties of the starch paste. The properties of the paste depend on many factors including botanical source, amylose content, amylose/amylopectin ratio, molecular weight, moisture content, shear rate, degree of granular disruption, additives, temperature, time, and chemical modification. Figure 2 illustrates the starch paste viscosity of different starches. Tuber and root starches swell more rapidly and have higher paste viscosity and solubilities than cereal starches. As the paste cools, amylose separates and retrogrades (crystallizes) quickly, whereas amylopectin requires a longer time to retrograde. Viscosity of the paste increases on cooling, and starches containing greater amounts of amylose show a larger increase in viscosity due to amylose retrogradation. Starch paste containing amylose will generally gel on cooling while waxy corn pastes, which contain no amylose, will remain fluid on cooling.

Nonfood Uses of Starches

Starch is used in many different industrial products (Table 2) and its function ranges from being an adhesive, binder, coating, flocculent, filler, fermentation ingredient, to being a viscosity modifier.

Starch Used in Paper Production

Approximately 1.7 billion kg of cornstarch went into the manufacture of paper for the 1996–97 year. The largest starch source for paper manufacture in the US is corn, but other starch sources can be and have been used. Most of the starch used in paper manufacturing needs to be modified. Starches can either be modified at the paper mill or purchased premodified. Currently, ~70% of the starch used in paper manufacturing is chemically modified, but in the past large amounts of unmodified starch were used in paper production. Starch use in paper manufacture is generally separated into three application areas: wet-end internal sizing, surface sizing, and coating.

Wet-end sizing can be divided among acid, alkaline, and neutral sizes. Alkaline conditions yield stronger paper, which allow mills to use more filler and less fiber, and thereby saving money. Increases in the use of alkaline sizing have led to an increase in the use of starch. Before the switch to alkaline sizing, manufacturers of uncoated paper used ~4.5 kg of starch per ton of paper. Mills using alkaline technology average between 4.5 and 8 kg of starch per ton of paper. The overall market for starch in wet-end sizing in North America was ~317 million kg in 2000. Waxy cornstarch holds half the market for paper starches used in the alkaline process. Starch is used in the wet-end process to improve strength and product appearance. Starches used for sizing may be unmodified or specially modified, uncooked, cooked before addition, or pregelatinized and dried. Cationic starches, which are starch derivates, are the preferred wet-end starch additives. By being positively charged, they are

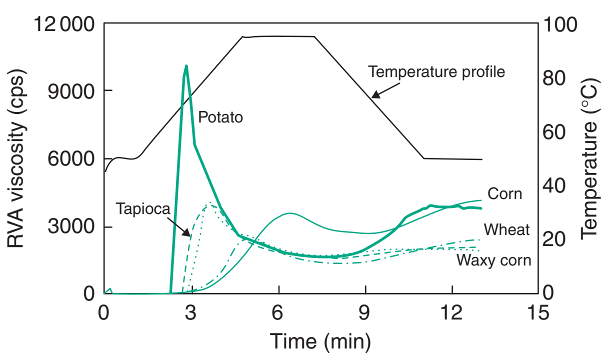

Figure 2 Pasting profiles of unmodified native starch. The pasting viscosity and temperature time profile were determined using a Rapid Visco Analyzer.

attracted to the negatively charged cellulose and the negatively charged fillers. This increases fiber to fiber and fiber to filler bonding, thereby increasing the strength and filler retention. These starches provide strength and drainage, as well as improved filler retention, in contrast to using native cornstarch.

The largest volume of starch used in paper production is for the purpose of surface sizing. Surface sizing improves the paper's finish, gives a better writing and printing surface, and minimizes lifting. Sizing is accomplished by running the paper through a sizing solution and then through sizing rolls. These rolls press the sizing into the paper and remove the excess from the surface of the paper. To make the sizing solution, paper mills usually purchase unmodified and unconverted starch and convert the starch at the mill. Preconverted starches such as acid modified, oxidized, acetylated, and hydroxyethylated are also widely used. Cooked unmodified starch is too high in viscosity for most sizing operations. Consequently, the viscosity of the starch paste is usually reduced. This is normally done at the mill by enzyme conversion, thermal conversion, or thermochemical conversion.

Paper coating refers to the addition of pigment, adhesives, and other materials to the surface of paper. The procedure is commonly called color coating. Some older literature refers to the procedure as pigment coating. The coating is done to provide whiteness, brightness, gloss and opacity, as well as an adequate surface for printing. The adhesive must act as a binder for the pigments, but also must act as a carrier for the pigments. Coating starches need to have lower viscosities than other starches used in the paper industry, because there needs to be a significant amount of starch present to bind the pigments and still be applied as a film. Due to the higher-starch solids, there is a greater potential for retrogradation to occur. Therefore, hydroxyethyl starch is an excellent coating binder. However, higher cost usually limits its use in conventional coatings. Most starches used in coating applications have been enzymatically converted to achieve higher starch levels in the coatings. Continuously enzyme-converted starches have lower viscosities and a more stable paste than those of batch-converted starch of the same solid content. Thermochemical conversion of starch with oxidants is capable of producing high solids coating binder at low cost. Compared with other binders such as latex, starch has a lower adhesive strength, but is usually less expensive. Some coatings contain a mixture of starch and more expensive binders to obtain a compromise between adhesive strength and cost.

The other large consumers of starch in the paper industry are the corrugated board manufacturers. Nearly all the corrugated board produced uses starch as the adhesive component. Corrugated board is a combination of liners (flat) and fluted paper. The material to be fluted is first softened by heat and moisture and then passed through a corrugated roll to form the flutes. Adhesive is applied to the tips of the flutes and to the face of the liner. The two are brought together under heat and pressure to form a single-facer web. A second liner is added to the single-facer web under similar conditions to form a flute double backer that is used in the familiar shipping containers. Additional single facers can be applied to double backer to build double and triple wallboard. Various weights and thicknesses of liners are used to produce corrugated board of different strengths for various applications.

The material used to join two layers of corrugated board is usually a two-phase starch adhesive. The liquid or carrier phase contains cooked (15–20% of total starch) starch, sodium hydroxide, and water. The solid phase contains raw starch, borax, and water. The total solids of the adhesive are ~20%. The sodium hydroxide is added to increase wetting of the cellulosic fibers and reduce gelatinization temperatures of the starch. The borax is used to cross-link the carrier starch and increase water-holding capacity. When the adhesive is applied to the heated flute tips, the raw starch is gelatinized in place. Then the fluted tips are brought into contact with the liner and passed through a roll to bond the material permanently.

Large amounts of starch or starch-based adhesives are used in the manufacture of bags and sacks. The three types of bag adhesives used are side seam, bottom paste, and cross-paste. The formulations of the adhesives for the three types of adhesive operation are quite different. During production of a single-layer bag, the paper is formed into a tube with the tube held together by side-seam adhesive. This adhesive needs to be slow drying, nonpenetrating, and made up of low solids having a high dry-bond strength. Side-seam adhesives usually contain white dextrin or acid-modified starch, so the viscosity will not be high. The adhesive needs to have low viscosity, because it is pumped to the applicator. Bottom-paste adhesive is used to close the bottom of the bag. This adhesive needs to have greater tack than the side-seam adhesive so as to keep the bag from reopening at the bottom seam. The bottom paste can be made from either white dextrin or starch and has a much greater viscosity than do side-seam adhesives. The cross-paste is very similar to the side-seam adhesive and is only used in the production of multiwall bags. Water resistance of bag adhesives can be improved by the addition of urea–formaldehyde or poly (vinyl alcohol).

Starch-Based Adhesives

Adhesives are used in a variety of applications, with more than 1000 different types of natural and synthetic adhesives used to manufacture many materials. Natural adhesives have ~32% (or 1.8 billion kg) of the adhesive market. Natural adhesives are derived from corn and wheat starches, lignin, vegetable oils, rubber, and animal-based proteins. Starch-based adhesives are the largest segment of the natural adhesive market. Approximately 60% (1.2 billion kg) of the natural adhesives produced and consumed in the US were derived from corn and wheat starch. Environmental concerns have spurred the use of natural adhesives that have better biodegradability over their synthetic counterparts. The success of some starch-based adhesives can be directly related to solid-waste disposal problems and recycling operations. Starch-based adhesives are now preferred in some types of automated systems because of easy equipment cleaning and flow characteristics.

Starches must be converted before they can be used as adhesives. Methods of conversion include heating, oxidation, alkali, and acid treatment. Dextrins are also starch conversion products. They are produced by dry-roasting starch with an acid catalyst. Starches such as potato, tapioca, and sago are generally easier to convert to dextrins. However, due to the low cost of cornstarch, it is most often used to produce dextrins in the US. Dextrins can be divided into three categories based on their manufacture: white dextrins, yellow dextrins, and British gums. Dextrins are used as adhesive components in bag manufacture, lamination, carton seals, stamps, labels, envelope flaps, and tapes.

Other Uses of Starches

There are numerous other uses of starch that make up many niche markets. Starch is an excellent binder and is used in the manufacture of charcoal briquettes, ceramics, sand molds, gypsum board, crayons, and chalk. Starch used as a binder in foundry applications is expected to grow to over 61 million kg. By using starch in ceramics, few hazardous air pollutants are released during firing in contrast to the pollutants released by bitumen, pitch, or lignin sulfate.

Starch has a long history in the textile industry, but the volume used has declined as the industry has moved out of the US. About 80% of the starch consumed in textiles is used as warp sizing. Most of the starches used in warp sizing are modified. Various starches are coated onto yarn to increase strength and abrasion resistance during weaving, which are removed by washing (desizing) the finished fabric. Starches are also used for textile finishing. The finishes are intended to improve the appearance, "feel," and draping qualities of the material.

Starches are used in oil-field applications as viscosity modifiers and to prevent drilling-fluid losses. Drilling fluids are thixotropic solutions used to cool the drilling bit and to suspend solids. High viscosity is needed at low shear to suspend solids and low viscosity is needed at the high shear region around the drill bit where rapid fluid movement is needed to cool the bit. High viscosity is also needed to reduce drilling fluid loss. Starch use as drilling fluids is restricted because starch stability above 107°C is limited, it is highly susceptible to bacterial degradation, and starch solutions have reduced permeability when injected into cores.

Chemicals are produced from starch either by fermentation or biochemical production. Because starch yields pure dextrose upon hydrolysis, it is now being used in many fermentation processes. Ethanol is the chemical produced in greatest quantity from starch. Other chemicals produced from fermentation include acetic acid, citric acid, lysine, lactic acid, and gluconic acid. The fermentation of glucose to lactic acids, from a mass balance point of view, is better than fermentation of glucose to ethanol. The molar yield of lactic acid is 2 mol of lactic acid per mole of glucose where commercial strains are used in anaerobic fermentation. Fermentation of lactic acid does not produce carbon dioxide as ethanol fermentation does. Other alcohols besides ethanol can also be fermented from converted starch or glucose such as butanol and isopropanol. Butanol and acetone can be produced by one of the oldest industrial bacterial fermentation processes (Weizman process) dating back to 1916. The yield of solvent and the ratio of butanol and acetone vary depending on the bacterial species used. Other chemicals can also be fermented from glucose such as butyric acid, formic acid, and acetaldehyde.

Polyhydroxy compounds can be made from starch. Glucose is the most common polyhydroxy compound obtained from starch. Yields obtained from acid or enzymatic depolymerization are ~90–95%. Glucose can be converted to a variety of cyclic and acrylic polyols, aldehydes, ketones, esters, and ethers. The most widely used polyol made from glucose is sorbitol. Its functional properties (e.g., sweeteners, humectants, and bulking agents) make it suitable for a variety of applications.

New and Future Uses of Starch

Since the 1980s, there has been a keen interest in replacing petroleum-derived, disposable plastic articles with biodegradable polymers. Plastics

intended for one-time use such as food packaging are difficult to recycle and constitute more than 7.7 billion kg a year market in the US alone. Because of starch's biodegradability, relative low cost, and ready availability, it has received considerable attention as an additive to impart biodegradability.

Starch can be used to make plastic-like materials in many ways. A loose-filled packaging material containing 95% starch was first introduced in 1990. Expanded packaging foams (peanuts) are made by extruding moist starch where water serves as the blowing agent. The original foam was prepared from a slightly hydroxpropylated high-amylose cornstarch. A small amount of poly (vinyl alcohol) was co-extruded with the starch in the presence of 16% moisture. The commercial loose-fill foams on the market generally contain more than 90% starch. Starch-based loose fill has now captured ~15–20% of the 4 million kg per year loose-fill market. Starch-based loose-fill foams have two main drawbacks: (1) its resilience is not as good as that of expanded polystyrene (ESP) and (2) the bulk density of the starch-based loose fill is greater than EPS loose fill. Greater bulk densities of starch-based loose fill make it more expensive per volume basis. It also adds more weight to the freight cost, as more of it is needed to cover the same volume. Starch-based loose fill does have the market advantage of being water dispersible and biodegradable. It also has the unexpected property of being antistatic. Applications for antistatic loose fill include its use in packaging of static-sensitive electronic components, foods, and drugs.

Thin-walled molded articles such as plates, cups, trays, and package cushioning (Figure 3) can be prepared by cooking starch in a mold. This technology is similar to waffle manufacture in the food industry.

Figure 3 Starch-foamed articles manufactured by baking technology.

An article is prepared by feeding aqueous starch slurry into a mold, with subsequent heating, and evaporation of the water. Molded articles can be made that contain 100% starch, but plant fibers, minerals, and plasticizer are usually added to improve the physical properties. Some items are already on the market in Europe and the US. Potato is the starch source most often used in the manufacture of these foamed articles, due to its greater foaming ability and its lack of odor. Cereal starches can be used where it is feasible.

Gelatinized starch, referred to as destructured starch, is used to make starch-based plastic. The term "destructurized" describes starch extruded at 5–30% moisture under elevated pressures and temperatures that are above its glass transition temperature and melt temperature. Starch that is prepared in this manner is thermoplastic and will flow upon heating. The thermoplastic starch resins usually contain various synthetic polymers (poly(vinyl alcohol), poly(ethylene-co-acrylic acid), polycaprolactone, and poly(ethylene-co-vinyl alcohol)), plasticizers, and lubricants that improve the properties of the resin and/or the properties of the final product. Thermoplastic starch resins generally contain at least 60% starch. These types of starch-based resins can be injection-molded into cutlery and golf tees, as well as blown into leaf and lawn compost bags and mulch. They also can be blow-molded into bottles and other containers. Unfortunately, starch-based resins have not made much of an impact in the market. This is mostly due to their greater cost and their physical properties being inferior to comparable synthetic resins.

Granular starch has been used as a filler in some types of plastic since the 1970s. Generally, starch is added to allow for or increase the biodegradation and/or lower the cost of the final plastic product. In these systems where starch is a filler in a composite, starch is diluting the resin, which is the continuous phase. This can lead to the reduction of some of the physical properties of the composite such as tensile strength, impact strength, and elongation. The reduction of tensile properties usually limits granular starch contents in composites to 40% or less. Much of the early work was done using starch in nonbiodegradable synthetic polymers such as polyethylene and polyvinyl chloride. In the early 1990s, new biodegradable polymers began to be produced such as poly(β-hydroxybutyrate-co-hydroxyvalerate), poly(ε-caprolactone), and poly(lactic acid). These new polymers had excellent properties, but were more expensive than their nonbiodegradable counterparts. Because of starch's biodegradability and low cost, it was naturally thought of as a possible filler in these new polymers

to reduce the overall cost of the resins. These filled composites suffered from the same problem as the nonbiodegradable filled synthetic polymers that being a reduction of their tensile properties.

Food Uses of Starches

Currently, ~15–18% of the starch produced in the US is used in food. Starch serves many functions in food such as thickeners, gelling aids, texturizers, emulsifiers, bulking agents, adhesives for coatings, water binding, and fat substitutes. Table 3 lists the food applications of starches in food. Using starch as a food ingredient requires that the functional properties of the starch match a particular application. Table 4 lists some of the functional properties of native starches.

Granular starch is commonly used as dusting agents for candy, starch molds for gumdrops, and as a carrier for baking powder. Smaller granular starch or starch particles ranging from 1 to 2 μm have been used as fat substitutes, because they resemble fat micelles.

Most food uses of starch require that the granular structure be disrupted and the starch polymers released. Native starches, although widely used in the food industry, have limited resistance to the physical conditions used in processing. To improve the effectiveness of starch as a functional ingredient, native starches are chemically and physically modified. Starch can be physically modified in a number of ways such as using different drying techniques, redried starches, agglomerated starches, and cold-water-swelling starches. Combinations of different starches are also employed to achieve the functional effectiveness needed to meet processing needs. Native starches without chemical modifications are now finding greater acceptance in food products due to consumers' demands for natural products. Starch manufacturers have developed native waxy starches that can withstand extremes in heat and shear used in food processing. These native starches can be used in hot retorts and hot filled foods. They also work well in dressings, soups, condiments, yogurt, and, puddings.

Table 3 Food products using native starch

Baking snack foods	*Frozen desserts*

The primary function of a starch in the food industry is to control viscosity. It is used to thicken, add texture and to control viscosity in a variety of prepared foods ranging from canned foods and salad dressings to pie fillings and puddings. Starches used during retort are fill viscosity starches designed to give viscosity during the initial mixing and filling process of canning. A viscosifying starch is used to retain viscosity during retort and as such cannot break down at high temperatures and when shear is applied. For salad dressing, starch is needed for both texture and viscosity control. High-amylose starches are used to provide the set (or spoonable nature) and mouth feel, whereas a waxy starch would provide the viscosity control. Pourable salad dressing uses starch to modify the viscosity, shorten the texture, and add creaminess to the dressing. Starch is used in fillings to modify the viscosity, add stability, and to give smooth short texture. The starch should also not mask or alter the flavor of the filling. For fruit fillings, it is important that the starch gives a clear gel.

Analysis of Quality

A Gunaratne and H Corke, The University of Hong Kong, Hong Kong, People's Republic of China

Introduction

Starch is the main polysaccharide produced in photosynthetic tissues. Recently, there has been a growing demand for starch in both food and nonfood industries because of its wide array of applicability in diverse systems. Functionality is the key for the industrial utilization of starch. Functional properties can be defined as the characteristics that govern the behavior of a food component during processing, storage, and preparation. Factors such as botanical source, structure and physicochemical properties, and pretreatments of starch directly affect functional properties of starch. Analysis of starch-related functionality should provide a clear picture of the relevant property that will allow better use of starch in food and nonfood systems, for example, to maintain consistent quality and functionality of starch-based products in every batch, otherwise the product will not survive in the competitive market. Methods that are implemented for the analysis of starch functional properties should be simple and fast, technically feasible, nondestructive, and able to provide reproducible results with high accuracy. Although several methods have been developed recently to monitor some of the functional properties, individual methods are sometimes not capable of providing adequate data on all the dimensions of a functional property,

especially in the determination of retrogradation and gelatinization. Therefore, it is often worth applying at least two methods to get complementary data. This article aims to discuss some functional properties of starch from the perspective of the applicability of methods that are currently employed to determine those properties.

Properties, Functions, and Analysis of Starch Macromolecules

Amylose

The two major compounds of starch are amylose and amylopectin. The two polymers are structurally different, the minor component, which is linear, consisting mainly of $\alpha(1-4)$-linked glucose. However, in some starches, amylose chains have shown a slight degree of branching. Incomplete conversion to maltose by β-amylase suggests the presence of branched points in the amylose polymer. The branched chains can also act similar to unbranched chains. Amylose isolated from tuber and root starches such as potato and cassava has a larger molecular weight than that isolated from cereal starches such as maize and wheat. Although amylose is a linear molecule, its conformation tends to change due to the large number of hydroxyl groups that can produce higher hydrogen bonding capability with strong internal forces. The conformation of amylose has been the subject of controversy and has been shown to vary from helical to an interrupted helix, to a random coil. In alkaline solutions (KOH) and dimethyl sulfoxide (DMSO), amylose probably has an expanded coil conformation, while in water and neutral aqueous potassium chloride solutions, it is a random coil with short, loose helical segments. Although helical conformation is common in amylose, double helices form when different helices are packed together. The helical arrangement of amylose forms a hydrophobic core inside the amylose molecule, which permits complexing with guest molecules such as lipids and iodine. The amount and molecular characteristics of amylose have a significant influence on starch functionality. Higher amylose content decreases the granular swelling power, whereas increasing amylose concentration decreases the gel stickiness but increases the gel firmness. Reassociation of amylose chains on cooling of a starch paste shrink the starch gel resulting in water accumulation on an aging gel, which decreases the storage stability and usually the quality of an affected starch-based food product.

Methods used in amylose estimation Conventional quantitative determination of amylose is based on its ability to form a deep blue color complex with iodine. Amylose content of starch therefore can be quantified either by spectrophotometric means or by potentiometric titration. Table 1 shows amylose content of some common starches. However, interference from amylopectin and other intermediate materials in the blue color formation reaction biases the estimation of actual content of amylose. Amylopectin–iodine complex is not stable due to shorter unit chain length of amylopectin, but long chains of amylopectin, e.g., long B chain of waxy maize amylopectin can bind with iodine in a similar way to amylose. This would lead to an overestimation. Despite shortcomings such as this, and the time-consuming nature

Table 1 Some physical and chemical properties of common starches

Starch	*Granular size (μm)*	*Granular shape*	*Amylose (%)*	*Swelling power at 95°C*	*Solubility at 95°C*	*Taste*
Barley	2–35	Round, elliptical, lenticular	22			Low
Maize						
Regular	5–25	Round, polygonal	26	24	25	Low
Waxy	5–25	Round, oval	~1	64	23	Low
High amylose		Round	Up to 80	6	12	Low
Potato	15–100	Egg-like, oyster indentations	22	1000	82	Slight
Rice	3–8	Polygonal clusters	17	19		Low
Rye	2–35	Elliptical, lenticular	23			Low
Sago	20–60	Egg-like, some truncate forms	27	97		Low
Sorghum	5–25	Round, polygonal	26	22	22	Low
Tapioca	5–35	Round, oval, truncated on side	17	71	48	Fruity
Wheat	2–35	Round, elliptical, lenticular	25	21	41	Low
Oats	2–10	Polygonal, compound	27			Low

of the assay, the amylose–iodine reaction is still the basis of the most widely used method to determine amylose content of starch because of its accuracy, reproducibility, and easy operation. However, the excessive time needed limits its use in quality control applications. Instead of conventional thermal dissociation of amylose in DMSO, low-temperature gelatinization in CaClB$_{2B}$ could be employed to reduce the time requirement. High performance size exclusion chromatography (HPSEC), that has shown a good correlation with blue value measurements of amylose content, can be employed to separate starch and de-branched starch. Ability to directly monitor the effect of de-branching on the molecular size distribution of starch and high-molecular weight linear amylose content from this technique provides the estimation of long-chain amylopectin chains that contribute to the apparent amylose content. Recently another technique that is able to eliminate the effect of long-chain amylopectin in the estimation of amylose content has been introduced. In this method, starch completely dissolved in DMSO is subjected to de-fatting with ethanol. The precipitate after de-fatting is dissolved in acetate/salt solution. A special reaction mixture (concanavalin-A) is then added to the solution to precipitate the amylopectin component and the resulting supernatant after centrifugation contains only the amylose component. However, a comparative study of size exclusion chromatography (SEC), differential-scanning calorimetry, iodine-binding capacity (IB), and concanavalin-A, where SEC was used as the reference method, has revealed that IB, differential-scanning calorimetry (DSC), and concanavalin-A resulted in an overestimation in the determination of amylose content of mutant maize starches (Table 2). As other alternative methods to the conventional iodine–amylose complex formation, spectroscopic methods have been developed recently. These techniques provide advantages such as ease of sample preparation, speed, and applicability to online monitoring in the process control situation compared with other techniques. Near-infrared (IR)-reflectance analysis has been successfully introduced in determining the amylose content of waxy, normal, and high amylose maize, unground brown or milled rice, and whole grain maize samples. Raman spectroscopy on the other hand is becoming more popular as a quantitative analytical technique in the food industry and has shown potential applicability in the estimation of amylose content in maize starches.

Amylopectin

Amylopectin, the highly branched molecule, is usually the major component in the starch granule with $\alpha(1-4)$-linked glucose linear chains and $\alpha(1-6)$-linked branch points. Crystalline domains of the starch granules are due to the clustered branches of amylopectin chains that are packed together, whereas the free amylose, amylose complexed with lipids, and branch points of the amylopectin are found in the amorphous region. Alternative arrangement of crystalline and amorphous region was proposed for the semicrystalline starch granule. However, there is no clear demarcation between amorphous and crystalline regions. Crystalline region is less susceptible to enzymatic hydrolysis, water penetration, and other chemical reactions than amorphous region. Amylopectin has a lesser tendency to gelation, retrogradation, and syneresis because of the branched structure. The amount of amylopectin varies among different starches. Waxy varieties contain almost 100% amylopectin. The extent of functional characteristics of starch (viscosity, gelatinization, solubility, texture, gel stability, retrogradation, shear resistance) are directly affected by the amylose/amylopectin ratio. Although amylopectin is the major component of the starch granule, there is no convenient method developed for direct estimation of amylopectin and studies on amylopectin are dependent on development of enzymatic and instrumental methods. Average structural properties of whole molecule and impact of internal structure of clusters on crystallization have been studied by means of enzymatic and SEC. It has been shown that the combined application of preparative and analytical size exclusion chromatography with multiple detection, precipitation techniques, and enzymatic de-branching provides the most detailed analytical insight on the microstructural properties of amylopectin.

Function Related to Morphological Characteristics of Starch Granules

Granules are the basic physical structural unit of starch. The size, shape, and other morphological characters of starch granules are extremely diverse (Table 1). The shape of the starch granule can be spherical, disk, polygonal, or elongated. In general, cereal starches have smaller granules compared to tuber and root starches. Most tuber and root starch granules have a simple size distribution. In some starches, such as barley and wheat, two different granular size populations exist, i.e., a bimodal distribution. Granular size and morphology have recently received more attention, e.g., the size of granules is important in determining taste and mouth feel of some starch-based fat mimetics. Some specific industrial applications of starch are related to size and the size distribution of starch granules. For example, the small size of rice starch granules makes it highly suitable for laundry use. Most of the physicochemical properties of native starch are highly correlated with the size of the starch granules. Larger size granules tend to swell more than smaller granules, whereas smaller size granules are more susceptible to enzymatic hydrolysis. The outer surface of starch granules also plays a key role in many applications of starch. Electron microscopic images have revealed that tuber and root starches show no sign of any pores on the granular surface. However, pores are present on the surface of maize, sorghum, and millet starch granules. Pores on granule surfaces increase accessibility of α-amylase to the granule interior resulting in increased enzymatic hydrolysis. Microscopic analysis provides information on surface features and size of starch granules.

Characterization and Analysis of Starch Thermal Properties

Gelatinization

Gelatinization is one of the most important processes affecting starch. It occurs when starch is heated in excess water, when irreversible granular swelling, native crystallites melting, loss of granular order, loss of birefringence, and starch solubilization take place. The extent of these changes depends on type of starch, starch concentration, temperature, presence of other solutes, and shear applied during the gelatinization process. As a result of the above changes during gelatinization, the starch paste develops viscosity, the basis of most technological usefulness of starch as an ingredient in food and nonfood applications. In the majority of food applications, starch functions (e.g., imparts texture on consumption) in a gelatinized form. Several concepts have been proposed to explain the gelatinization process. Granular swelling acts primarily as a driver to destabilize the starch crystallites. Recently, a model was proposed to explain the phenomena involved in gelatinization and hydration of starch based on the side-chain liquid crystalline. In this model, lamellae in starch are considered in terms of three components – (1) backbone, (2) side-chain, and (3) double helices. The degree of mobility of these three components, coupled with the helix–coil transition, give starch its distinctive properties in gelatinization. Gelatinization is influenced by many factors such as, botanical source of starch, water content, and added solutes. Several methods have been proposed to study the effect of water content on thermal stability. Depending on the water content available during gelatinization, changes in endothermic transition have been detected in terms of number and the position of the differential scanning calorimetric endotherms. Only one endotherm is detectable at higher levels of moisture content while two endothermic transitions are reported at the low-moisture-content level for some starches where low temperature and higher temperature endotherms are designated as G1 and M1 respectively (Figure 1). In addition to two endothermic transactions at lower moisture content, peaks are shifted to higher temperature, indicating need for higher thermal energy to melt the starch crystallites at low moisture content. If there is sufficient water available in gelatinization, then crystallites melt cooperatively, resulting in a single endotherm. Two endothermic transition peaks in insufficient water could be attributed to the differences in the stability of starch crystallites, which melt over different temperatures, less stable crystallites melt first and the

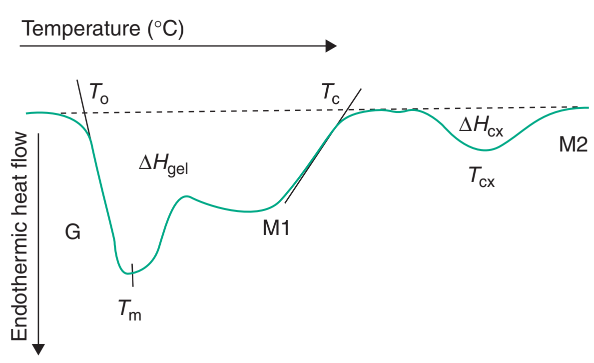

Figure 1 Schematic representation of DSC thermograms obtained for wheat starch heating. (Eliasson A-C (2003) Utilization of thermal properties for understanding baking and salting processes. In: Kaletunc G and Breslauer KJ (eds.) *Characterization of Cereals and Flours*, pp. 65–115. New York: Marcel Dekker.)

others are next causing the second endotherm. Redistribution of water between crystalline domain and gelatinized starch could also result in two endothermic transitions, in which the first endotherm could be attributed to melting of starch crystals in excess water. Much research has been conducted to investigate the influence of added solutes such as sugars, emulsifiers, and electrolytes (such as sodium chloride), which are widely applied in food industry on starch behavior. Sugars have shown to increase the gelatinization temperature but not to affect endothermic heat absorption. Quality of various food products, bread and cakes, thickening and gelling of sauce, pie filling, and extrusion of cereals are highly dependent on starch–water interaction. Increased gelatinization, when sugars are added to starch paste could be due to decrease of water availability for the gelatinization, binding water to sugar molecules. However, it was reported that sugar acts as an antiplasticizer rather than gelatinizer through the effect on water-binding capability. Increased sugar concentration decreases the plasticization effect requiring more heat energy to achieve the gelatinization. The extent of the influence of sugars on gelatinization, swelling, and viscosity differs depending on the type of sugars and salts used when compared on a molar basis. Monosaccharides are less effective than disaccharides except maltose; among disaccharides, sucrose is more effective.

Methods in the analysis of starch gelatinization There are several methods to analyze the gelatinization process, such as DSC, Kofler hot-stage microscopy, light microscopy, electron microscopy, X-ray crystallography, enzymatic analysis, nuclear magnetic resonance (NMR), pulsed nuclear magnetic resonance, small angle X-ray scattering, and small angle neutron scattering, Brabender visco-amylography (BV), and Rapid Visco Analysis. DSC, the most widely used method, measures the dissociation parameters, T_o (onset), T_p (peak), T_c (conclusion), and ΔH (endothermic heat absorption), of starch crystallites in gelatinization (Figure 1). ΔH is the area below the transition endotherm. Gelatinization parameters of starches from different botanical sources measured by DSC are presented in Table 3. In addition, DSC can be used to study the glass transition temperatures of various starchy food products. Gelatinization temperatures are influenced more by the granular architecture than the amylose–amylopectin ratio and depend on the degree of starch crystallite perfection, whereas endothermic heat absorption reflects the quality and amount of starch crystallites. Analysis of gelatinization parameters of starch using DSC was first reported in 1971.

Table 3 Gelatinization parameters of some starches measured by differential scanning calorimetry

Starch	*Starch–water ratio*	T_o	T_p	T_c	T_o-T_c	ΔH

Gelatinization parameters measured by DSC can be affected by sample preparation, baseline application, pan selection, method of adding water, sample mass, heating rate, and moisture equilibration time. Thermal behavior of amylose–lipid complex as well as formation of amylose–lipid inclusion with various molecules such as fatty acids and emulsifiers can also be detected by DSC. Characterization of amylose–lipid complex in cereal starches and influence of amylose–lipid complex on starch properties are well documented. Some of the internal lipids in cereal starch is thought to be complexed with amylose to form the amylose–lipid complex, which is dissociated at higher temperature (M2 endotherm in Figure 1) than that of normal starch crystallites (Figure 1 and Table 4). Although DSC is widely used to study gelatinization, the small sample size used can limit its real applications. In a comparative study of maize starch gelatinization with DSC and NMR, it was reported that NMR could provide much better performance in the analysis of gelatinization for larger samples than DSC. Gelatinization temperature of

Peruvian carrot, potato, and maize starch measured by Rapid Visco Analyzer (RVA) and BV, and DSC have shown different values for different methods. This indicates the need for multiple analytical techniques for a meaningful understanding of gelatinization along with careful specification (and preferably standardization) of experimental conditions used. Table 5 shows the differences in gelatinization parameters measured by different techniques for the same starch.

Pasting properties

Starch heated in excess water undergoes various changes as a result of heat and moisture transfer. Gelatinization and pasting occur in the same system and have often been used to describe all the changes that occur. Gelatinization may be used to refer to early changes whereas pasting includes later changes. Starch gelatinization is defined as the collapse of the starch granule manifested in irreversible melting, loss of birefringence, and starch solubilization. The point of gelatinization, and the range over which it occurs is governed by starch concentration, method of observation, granular type, and heterogeneity. Pasting is defined as the phenomena following gelatinization in the dissolution of starch, involving granular swelling, exudation of molecular components from the granule, and eventually total disruption of the granules. The schematic representation of granular changes and viscosity development that occurs during pasting is shown in Figure 2.

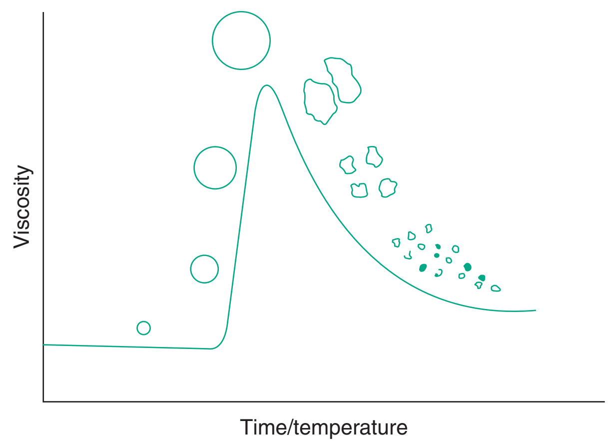

Figure 2 Schematic representation of granular changes and viscosity development during starch pasting (Daniel JR and Whistler RL (1985) Principal changes in starch during food processing. In: Richardson TR and Finley JW (eds.) *Chemical Changes in Food During Processing*, pp. 305–326. Westport, CT: Avi Publishing Co.).

Measurement of pasting properties The BV is the most widely established method for determining pasting properties, although it has some methodological and geometrical shortcomings. This apparatus measures the development of viscosity when a starch–water suspension is subjected to a programmed heating and cooling cycle under a shear force. The temperature at which viscosity begins to increase is termed pasting temperature. With further heating, granular swelling increases the viscosity to reach a peak. Further heating at elevated temperature under shear force tends to disintegrate the swollen granules resulting in decrease of viscosity. Upon cooling the starch paste in the next stage, there is a tendency, mainly due to amylose chain reassociation, to increase viscosity. Therefore, a typical pasting profile exhibits three distinct viscosity developments, peak viscosity, hot paste viscosity, and cold paste viscosity (Figure 3). Pasting curves vary according to botanical source of the starch, starch concentration, and the programmed heating–cooling cycle chosen. Among the native starches, potato shows the highest peak viscosity, and generally, low peak viscosity and higher setbacks can be detected in normal cereal starches compared to tuber and root starches. Waxy cereal starches, on the other hand, behave

more like the tuber and root starches (Figure 4). According to the characteristics of pasting curves, starch has been categorized into four groups as, high swelling starch (potato, cassava, waxy cereals, ionic starch derivatives), moderate swelling starch (normal cereal starch), restricted swelling starch (cross-linked starch), and highly restricted starch (starches >55% amylose). The above four different categories of starch exhibit the following pasting properties respectively: high peak followed by rapid and major thinning during cooking; lower peak and much less thinning; no peak but maintain high viscosity during cooking; and no swelling to gave a viscous paste at normal concentration.

Because of some technical shortcomings with the BV, such as large sample size requirement and inability to program the temperature profiles, a more recent equipment, the RVA, has become popular for analyzing pasting properties. The RVA differs from the Brabender instrument due to rapid heating rate and stronger mixing action. However, controlled heating rate to 1.5°C min^{-1} in RVA provides similar results to those observed in the BV. Comparative study of pasting properties of cassava, "sago" (sagu), and arrowroot using Brabender and RVA has shown that both techniques provide similar pasting patterns (Table 6). Pasting curves of some of the starches determined by BV and RVA is presented in Figures 4 and 5.

Swelling and Solubility

Native starch granules are insoluble in water. Although small amounts of water can be absorbed at room temperature, granular swelling is limited in intact granules. During heating in excess water, after the onset of gelatinization, granules begin to swell rapidly, losing the polarization crosses. The extent of the swelling power and solubility depends on the magnitude of the starch chain interaction within the amorphous and crystalline domain, size of the starch granules, amylose content, bound lipids, starch

damage, temperature, and molecular characteristics and the amount of amylose–amylopectin ratio. Table 1 presents the swelling and solubility of some starches at 95°C. High amylose content lowers the swelling whereas larger granules show greater swelling. The swelling power and solubility provide information on the relative strength of bonding within the granules.

Methods used to analyze starch swelling Swelling volume, swelling power or swelling factor, all measure the extent of granular swelling at a given temperature, when starch is heated in excess water. However, swelling factor measures only the intergranular water content and hence reflects the true swelling of starch granules at a given temperature. Swelling power measures the weight of swollen starch sediment relative to the initial starch dry weight, and is expressed as the ratio of the wet sediment to the initial weight of the dry starch. Measuring the soluble carbohydrate that dissolved in the supernatant either by oven drying or colorimetric method enables solubility, the ratio between the amount of soluble carbohydrate to the initial weight of dry starch to be obtained. Swelling volume is a modified version in which programmed shaking of starch suspension is used instead of stirring, and measurement is of the volume expanded due to granular swelling. Swelling factor is the ratio of volume of swollen starch granule to the volume of the dry starch. Swelling factor measures only the intragranular water content. Calculation of the swelling factor is based on starch weight adjusted to 10% moisture assuming the density of 1.4 mg ml^{-1}. The basic principle of this method is the measurement of the volume of water absorbed by starch granules heated in excess water, based on the observation that blue dextran dye (molecular weight $2 \times 10P^{6P}$) will dissolve in supernatant and interstitial water. The advantages of this method over the others are the ability to measure the true swelling and the high accuracy.

Retrogradation Reassociation of starch polymers via hydrogen bonding in gelatinized starch on cooling is generally termed retrogradation, and is time- and temperature-dependent. Starch gels tend to undergo structural changes during storage as they are metastable and nonequilibrium systems. Both amylose and amylopectin are involved in retrogradation, where rapid amylose aggregation causes a short-term development of starch gel providing initial firmness. Branched amylopectin recrystallization, particularly outer branches of amylopectin molecule, is correlated with long-term development of starch gel. Several factors influence starch retrogradation, such as, starch concentration, storage temperature, initial heating temperature, chain length distribution of amylopectin, molecular size of amylose, lipids, and physical and chemical modification of starch.

Effect of retrogradation on quality of starch-based food products Retrogradation has desirable as well as undesirable effects on quality of starch-based food products. Mostly it is undesirable. Bread staling is one of the main undesirable effects of retrogradation. Although several factors contribute to bread staling, it has been found that retrogradation is the key physical change associated with bread staling. Retrogradation sometimes aids processing in some food products such as hardening of parboiled rice and to improve textural characteristics of certain types of noodles.

Determination of starch retrogradation Several methods have been developed to determine starch retrogradation, because of its great influence on industry-based food and nonfood products, such as DSC, X-ray analysis, rheological methods, and spectroscopic methods.

Differential scanning calorimetry Several studies on retrogradation behavior have been examined using DSC techniques. DSC is probably the best thermal analysis method to study the starch-aging process for different systems. However, dissociation parameters of stronger crystals that formed due to the association of amylose are usually difficult to detect using DSC, since those crystals dissociate at higher temperature (>120°C). Therefore, DSC usually measures the melting of recrystallized amylopectin, that occurs at the same temperature interval as gelatinization

(Figure 6), when reheating of retrograded starch gel, in which heat absorption, the area under the endotherm (ΔH), and transition temperatures can be detected (Table 7). Crystals formed by the association of amylose chains would be possible to detect using DSC pans, that can withstand a higher temperature range (Figure 7). Characteristic smaller endosperms were usually reported for the retrograded gel compared with the gelatinization endotherm of their native counterpart. However, it was reported that retrograded starch crystals melt over a wide range of temperature indicating the more heterogeneous crystal perfection than those of native starch crystals. Melting temperature indicates the perfection of recrystallized amylopectin, the quality and heterogeneity.

Although DSC has some advantages especially that it is not time consuming, has a wide range of applications, and measures directly, it has some weakness particularly its small sample size and inability to determine retrogradation in dilute starch paste. More often DSC coupled with X-ray analysis provides better performance in characterizing retrogradation.

X-ray analysis X-ray analysis can be applied to detect the presence and nature of crystallinity in native starch granules as well as crystals formed in aging starch gels. In native starch, the crystallinity is due to the amylopectin components and the crystal

domains are constructed mainly of A chains and outer B chains of amylopectin. Native starches can be categorized into three groups according to their X-ray diffraction pattern. The A type crystallinity is found mainly in cereal starches. Most tuber and root starches exhibit typical B type X-ray pattern and C type is intermediate between A and B types, shown in legumes, cassava, and some varieties of sweet potato (Table 8). X-ray analysis of retrograded starch has shown that aging gels form B-type crystals irrespective of the native starch. Some research using wide range and small angle X-ray diffraction, shows that crystalline formation in starch paste occurred primarily due to amylopectin aggregation, whereas amylose provides a template effect and highly ordered amylose aggregation does not necessarily possess a crystalline nature but accelerates the amylopectin reassociation. Recently, more information on bread staling has been revealed by X-ray analysis. Aggregation of starch polymers that formed crystals in bread staling was shown from X-ray analysis; however, NMR and FTIR techniques are better at detecting minor differences of starch polymer aggregation than X-ray analysis.

Rheological methods Measurement of pasting parameters, analysis of textural properties of starch paste using texture analyzer, and small deformation dynamic techniques oscillatory rheometry can be applied to the behavior of starch. Pasting behavior of starch indicates the trend of starch retrogradation. In a typical pasting profile, the magnitude of setback reflects the tendency of mainly amylose polymer reassociation in a starch paste. Several investigations have been performed to study the properties of aging breads using viscometry and have observed a tendency of decreased peak viscosity when bread staling progresses. Recently there is a growing interest, especially in industry, in use of texture analyzers that can directly and rapidly measure the textural properties such as hardness, stickiness, cohesiveness, adhesiveness, fracturability of starch paste (Table 9). Long-term reliability and accuracy, direct measurement, time saving, and technical feasibility of the texture analyzer increases its attractiveness among food technologists. The main issue which requires continuing work is that of instrumental to sensory correspondence, i.e., whether the texture analysis profile is adequately predictive of the sensory traits important to the consumer.

Many additional methods can be employed to detect retrogradation. No individual method is able to fully characterize all the events of the starch-aging process. DSC measures only the transition of heat energy in the melting of crystal aggregates, X-ray measures the presence and characteristics of retrograded starch crystals, and texture analysis provides textural parameters for the aged starch gel. Therefore, it is clear that a multiple analytical technique approach for the advance detection of retrogradation behavior is necessary. For example, a study of bread staling with multiple techniques, DSC, FTIR, and NIR, led to greater understanding of the process than would be possible with each individual technique used alone.

Chemistry

F L Stoddard, University of Wolverhampton, Wolverhampton, UK

Introduction

Starch is the major energy reserve of higher plants. This makes it a major energy source in the diet of humans and many other animals, including livestock animals grown for their meat and milk as well as pest animals which consume grains in storage. Starch comprises ~70% of the dry matter of the endosperm of a mature cereal grain and ~16% of the fresh matter of a mature potato tuber.

Starch may be loosely defined as a polymer of glucose which is distinguished from other glucans by a number of key features.

First, it is α-linked, unlike cellulose and other β-linked glucans. The majority of these links are α-1,4 (also written as α-(1 $\rightarrow$ 4)), leading to chains of varying lengths, and the chains are joined together by α-1,6 linkages. These branching points occur in a highly ordered fashion, leading to double-helix formation and a type of crystallinity, minimizing water-holding capacity. This feature is in significant contrast to glycogen, an α-(1$\rightarrow$4), (1$\rightarrow$6) mixed-link glucan found in animals and bacteria. Ordering in glycogen is very limited, so it holds much more water than an equivalent mass of starch. It is thus not as efficient an energy store where water availability is limited, such as in a dry, dormant seed.

Starch is deposited in granules between 1 and 100 μm in diameter within membrane-bound organelles. In the actively photosynthetic parts of the plant, these organelles are the chloroplasts, and in storage organs, they are the modified chloroplasts called amyloplasts. Granule structure has a number of features which are consistent across species, while granule size, morphology, and composition vary widely among species. These aspects as well as starch composition affect the processing properties of the starch.

The Monomer and Linkages

The building block of starch is D-glucose, in its hexagonal pyranose ring conformation (Figure 1). Carbon 1 of this ring is a highly reactive, aldehydic, "reducing" end. Most commonly, during polymer formation in a plant, it attaches to carbon 4 of another glucopyranose residue (Figure 2). When the monomers are α-D-glucopyranose, the resulting polymer is a chain of starch, and when they are β-D-glucopyranose, it is a chain of cellulose.

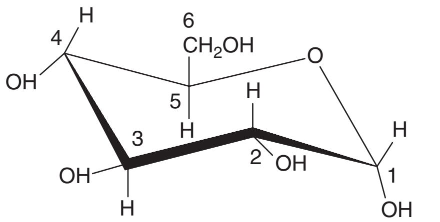

Figure 1 D-glucopyranose. As shown, this is the α-conformation. When the hydroxyl group and hydrogen attached to carbon 1 are in the opposite orientation, it is the β-conformation.

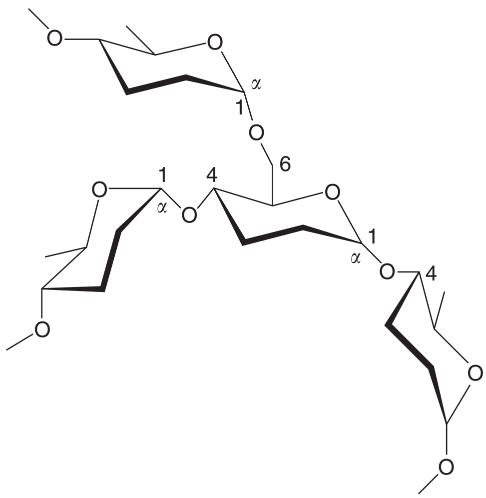

Figure 2 Glucose polymer with α-1,4 and α-1,6 branching types.

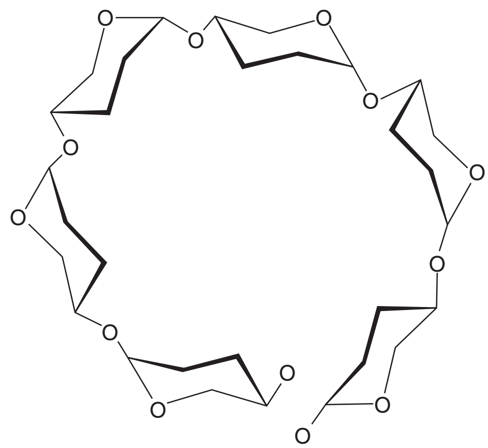

Figure 3 Helix of α-1,4 glucose residues, seen from above.

An α-1,4 linked glucan is at its most stable in a left-handed helix, with a complete turn taking six residues (Figure 3) and occupying 2.1 nm. Hydrogen bonding between adjacent glucose residues helps to stabilize the helix. The helix can allow a second parallel helix to fit into it, creating a double helix. The helical structure of starch is an important factor in its processing properties and in its enzymic degradation during digestion. Cellulose, in contrast, is highly crystalline, ribbon like rather than helical, and relatively few organisms have the appropriate enzymes to hydrolyze it.

The presence of α-1,6 bonds (Figure 2) allows the development of much larger and less soluble polymers through the introduction of branching points connecting glucose chains of various lengths. Starch is an excellent example of the evolutionary conservation of a successful structure throughout the plant kingdom.

Starch Polymer Types

Two subclasses of starch, "amylose" and "amylopectin," have been widely recognized, based on chain length, branching pattern, and overall mass. Both types have a single reducing group per molecule and a variable number of nonreducing ends. Most plant starches comprise about one-fifth to one-third amylose and the remainder amylopectin (Table 1). Plant breeders and geneticists have considerably enhanced this range since the beginning of the twentieth century.

Amylose is usually described as being "essentially linear." A typical amylose molecule comprises two to eleven chains of 200–700 α-1,4 linked glucose residues. The chains are connected by α-1,6 bonds, leading to an overall polymer size of 1000–5000 glucose residues and a molecular mass of $(1.6-8)\times 10^5$. Chain length and branch number are species specific. Within the starch granule, the amylose chain is present as a single helix. This is demonstrated by the ease with which it may be leached out of the granules by water at moderate temperatures and its full release at 60–80°C, whereas an amylose double helix should not be released until the temperature greatly exceeds 100°C. The single helix retains a hydrophobic channel or lumen along its axis, into which a fatty acid, for example, may interpolate. These amylose–lipid complexes have critical effects on the processing properties of the starch, as described below (starch-bound lipids). Amylose concentration increases during the course of starch deposition in the storage organ and, in maize, is greater in proximal than in distal grains.

Amylopectin is a much more complex entity and is usually described as "highly branched." The overall molecular mass is of the order of 10^6-10^8, making this polymer one of the largest known in nature. Chain length distribution is multimodal and there are three main types of chain. The A-type chain is the outermost in the branching pattern and contains 15–30 α-1,4 linked D-glucose residues. It is attached to a B-type chain by an α-1,6 bond between the

Data from a variety of sources.

reducing C1 of the A chain and a C6 of the B chain. The A-chain : B-chain ratio is commonly 1–1.5 : 1. The B-chain has one to several A-chains attached to it and is itself attached either to other B-chains or to the C-chain, which carries the reducing end of the polymer. The B-chain is classified as B1 to B4, with the numeral indicating how many crystalline lamellae, or zones of the starch granule, it passes through. A B1-chain passes through only one lamella and is similar in chain length to the A-chains. A B2-chain passes through two such lamellae and has a chain length of ~45–50 glucose residues. The B3- and B4-chains are correspondingly longer and rarer. The currently accepted model, supported by a range of analytical methods, is that the branching points are clustered within any given molecule and also coordinated in adjacent molecules, rather than random (Figure 4). The model shows double helices, often of an A-chain and a B1-chain, as the state of the outermost branches. The lumen of a double helix is smaller than that of a single helix and hence less likely to include guest molecules. In potato amylopectin, phosphate groups are attached to some of the hydroxyl groups of the glucose residues. This is associated with greater hydrophilicity and may contribute to the high swelling power of potato starch, which is 10 times that of many other starches.

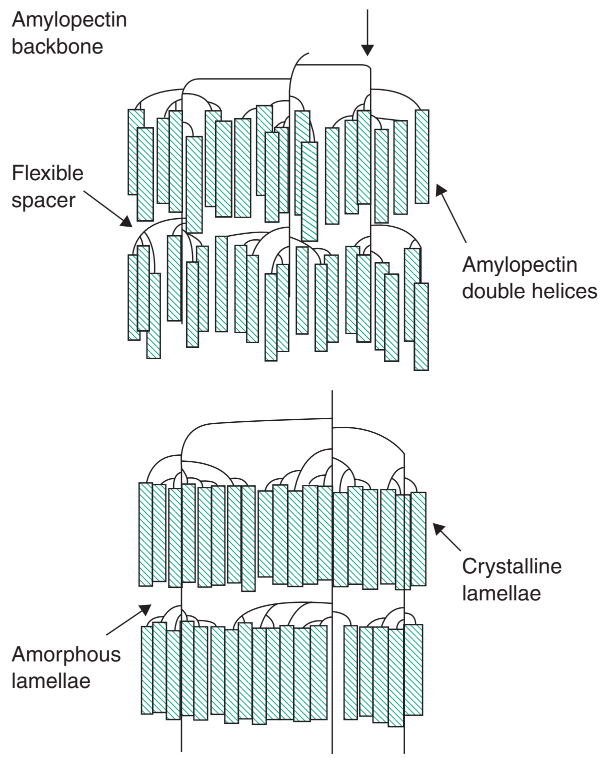

Figure 4 Representation of the amylopectin molecule as a liquid crystal. The shaded blocks represent double helices. In the dry state (top), they are disordered and in the hydrated state (bottom) they are aligned. (Reproduced with permission from Donald AM, Perry PA, and Waigh TA (2001) The impact of internal granule structure on processing and properties. In: Barsby TL, Donald AM, and Frazier PJ (eds.) *Starch: Advances in Structure and Function*, pp. 45–52. Cambridge, UK: Royal Society of Chemistry.)

Numerous biochemical tests have been devised to evaluate the relative proportions of amylose and amylopectin in a starch. One of the most common involves the use of iodine, which may be quantified in two ways. Amylose can bind 20% of its mass in iodide, whereas amylopectin binds less than 1%. This may be measured accurately, if slowly, by potentiometric titration. In a more approximate and considerably more rapid method, the light absorption of the solution may be measured. Chains of tri-iodide ions bound by the amylose helix absorb strongly at longer wavelengths of light, 600–640 nm, causing the starch–iodine solution to appear blue. Each turn of the helix holds about two iodine atoms. Shorter chains infrequently included in amylopectin helices absorb at a lower wavelength, 530–550 nm, and

confer a tan, reddish, or purplish color to the solution. Any lipid molecules in the solution compete with the iodide ions for the amylose helices and thereby reduce the apparent amylose concentration. Various authors have shown that simultaneous measurement of absorbance at two to six wavelengths across the visible spectrum greatly increases the accuracy of this method over the traditional measure at a single wavelength in the 600–640 nm range. High-pressure size exclusion chromatography is a modern method for amylose determination with a reasonable balance of throughput and accuracy.

"Intermediate material" was described in maize starch for many years, having some of the features of amylose and others of amylopectin, e.g., amylopectin-type branching but with much longer chains. This area is discussed further below.

Phytoglycogen is found in certain plant mutants such as sweet corn. It is due to a mutation in the gene for starch debranching enzyme or isoamylase. Its structure is very comparable to that of animal glycogen, and its lack of higher-order structure, such as double helix formation, allows it to remain largely water soluble. This aspect limits the amount of storage polysaccharide that can accumulate in a grain, so when it dries down at maturity, it is shrunken and wrinkled.

Levels of Organization

The next order of structure is an alignment of the short, stiff double helices of the amylopectin molecules. This takes place in two ways. First, they align parallel to each other, along the radius of the starch granule. This is what gives the polarization of light, leading to a characteristic "Maltese cross" appearance when starch granules are viewed between crossed polarizers in a microscope. Second, the double helices pack together in an energy-minimizing fashion (Figure 5). In some starches, generally those from tubers and stems, the packing is hexagonal with a lumen in the center, which leads to a consistent pattern, termed B-type, in X-ray diffraction. In other starches, mostly those from grains, the double helices pack much more closely, without a lumen, leading to a different, A-type, X-ray diffraction pattern. Starches from grain legumes and from most roots have an intermediate diffraction pattern, termed C-type, which implies that some of the hexagons have a lumen and others do not. A final X-ray diffraction pattern, V-type, is given by amylose which encloses a lipid chain. High-amylose maize gives a B-type diffraction pattern, suggesting that amylose does not pack as tightly as amylopectin. Some species of yam (*Dioscorea*) show A-type diffraction patterns and some B-type. Starches with the B-type pattern generally retain or take up more water than those with an A-type pattern.

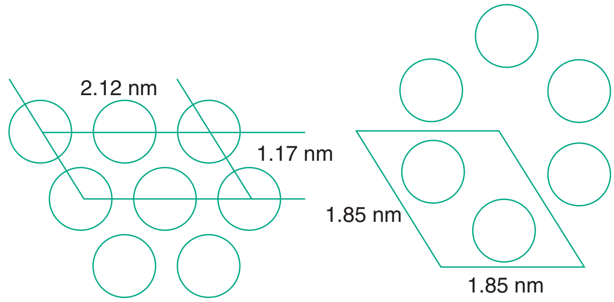

Figure 5 Packing of amylopectin double helices: left, monoclinic crystal giving A-type X-ray diffraction pattern; right, open crystal giving B-type X-ray diffraction pattern. (Modified from Parker R and Ring SG (2001) Aspects of the physical chemistry of starch. *Journal of Cereal Science* 34: 1–17.)

The crystalline double helices are thus aligned in a crystalline lamella. This alignment is possible because the branches in amylopectin are clustered, leading to an amorphous (noncrystalline) region (Figure 4). The thickness of this amorphous/crystalline ring is commonly 9 nm. This is commensurate with a helix of ~18 residues (6.3 nm) plus a few more residues to join with the B-chain in the amorphous lamella. This, in turn, accounts for the 15–30 unit length of the majority of amylopectin chains.

Alteration of packing can occur in the presence of gentle hydration, leading to the model that in the hydrated starch granule, the rod-like double helices on their flexible attachments function as a liquid crystal (Figure 4).

Stacks of ~16 amorphous/crystalline lamellae form semicrystalline layers of ~140 nm in thickness. These layers are separated by amorphous layers of comparable thickness. This level of order was visible in early electron micrographs. Experimental results published in 1962 suggested that these "growth rings" disappeared in plants grown in continuous light. Nevertheless, some controversy remains about the association of these rings with diurnal light cycles. Most starch granules show the alternating semicrystalline and amorphous layers across their entire cross-section. Certain double mutants in maize, however, show clearly biphasic growth. In *ae du* and *ae wx* lines, the core 30–60% (by volume) of the starch granule shows the typical concentric rings, but the remaining outer mass of the granule is shapeless and disorganized. It was proposed that there was a change in the relative expression of the starch synthetic enzymes and in substrate concentration.

Starch Granule Morphology

Starches of wheat, rye, barley, and many of their wild relatives in the cereal tribe Triticeae have biphasic granule initiation, rather than biphasic growth. One major starch granule, termed A-type, originates in each amyloplast. About 15 days into grain filling, membrane tubules appear around the equator of the A-granule and several subsidiary, B-type, granules form. At grain maturity, the A-granules are approximately lenticular or lentil shaped, with a long diameter about twice the short diameter and with a detectable equatorial groove. Mean A-granule diameter can be as low as 15 μm in diploid wheats such as *Triticum monococcum* or as large as 30 μm in some tetraploid and hexaploid *Aegilops* species, but is 20–25 μm in cultivated rye, barley, durum wheat, and common wheat (Table 1). The B-granules are roughly spherical and average 5–6 μm in diameter in most of these species. There are other differences between A- and B-granules. B-granules lack the central cavity or hilum found in A-granules and also in the granules of other species. They also lack at least one granule-bound protein and they can have amylose contents 2–4% lower than A-granules. With their greater surface area they adsorb more water per unit mass than A-granules. The factors determining A-granule size and B-granule concentration or initiation are the subjects of continuing research. Many scientists view a third population of small B-granules as a distinct C-granule type. This bimodal or trimodal granule size distribution is not found in any other group of plant species.

In maize, starch granules are spherical when isolated from "mealy" regions of the mature grain where there is space between the granules, but are polyhedral when isolated from "vitreous" regions where the granules have been in close physical contact since partway through grain filling. Faceted granule surfaces are thus attributable to restricted growing space rather than active differences in granule development. A-type granules of wheat and barley often show indentations where other granules have impinged on them. Oat and rice have compound starch granules. Grain legume starch granules are generally ovoid or elliptical, and root or tuber starches are usually round to ovoid.

Zero-amylose (waxy) starches have a fairly normal gross morphology. Granules of high-amylose starches, in contrast, such as those of amylomaize or wrinkled pea, are shapeless, fissured, and nonbirefringent. These features demonstrate the critical role of amylopectin in determining granule crystallinity and the much less critical role of amylose.

Starch-Bound Lipids

As mentioned above, long amylose chains and lipids can form complexes. The concentration of lipid in starch is very strongly correlated with the amylose concentration of the starch. The amylose–lipid complexes resist both their own leaching from the starch granule and also the entry of water into the granule. This latter aspect may be the biological importance of starch-bound lipids in the quiescent or germinating seed. Starch processing properties are also affected by the presence of bound lipid, which increases gel temperature and the temperature of maximum viscosity, decreases gel strength, and delays staling by interfering with retrogradation. Removal of lipids lowers gel temperature and increases peak viscosity.

Starch-bound lipids are generally either free fatty acids (commonly linoleic) or lysophospholipids. The ratio of these two classes differs among species (Table 2). In some species, di- and tri-glycerides are also found bound to starch. Lipid concentration of extracted starch varies up to tenfold depending on the extraction method.

Starch-Bound Proteins

Numerous types of protein are found in close association with starch granules, some on the surface and others bound within. The biological functions of some of these proteins remain to be determined. The surface

Table 2 Composition of selected starch-bound lipids

proteins tend to be smaller than the internal proteins. Altered sequences in the tryptophan-rich surface proteins, puroindoline "a" and puroindoline "b," have been strongly linked with difference in grain hardness, but their causative role in this difference is controversial.

Granule-bound starch synthase (GBSS), which has a relative molecular mass of ~60 kDa, is responsible for synthesizing amylose and is thus absent from so-called "waxy" mutants (currently identified in a wide range of crops including maize, barley, wheat, rice, and pea). Confocal laser scanning microscopy of fluorescent-dyed proteins has shown that GBSS is localized in concentric spheres within the starch granules of maize, wheat, and potato. These spheres appear to be the amorphous layers of the growth rings. Other unidentified proteins were shown by this method to be concentrated in the hilum of the granule. A large, 140–152 kDa form of starch branching enzyme (SBE I) has recently been shown to be associated only with A-granules, not B-granules, of wheat.

The total protein concentration of extracted starch is higher in cereal grains than in roots or tubers (Table 1), although the exact figure depends a great deal on the extraction method.

Dissociation Chemistry

Gelatinization has been defined as "the collapse (disruption) of molecular order within the starch granule, manifested in irreversible changes in properties such as granule swelling, native crystalline melting, loss of birefringence and starch solubilization." Pasting is what happens after gelatinization – "granule swelling, exudation of molecular components from the granule and, eventually, total disruption of the granules."

Starch granules in cold water can reversibly absorb 30% of their weight in water. When starch is heated in an excess of water, a sequence of events occurs as the kinetic energy of the polymer increases and the hydrogen bonds rupture. At the "pasting" or "gelatinization" temperature, between 60°C and 70°C, energy is absorbed in de-crystallizing the crystalline regions of the molecule. It also leads to an endotherm, as seen in the differential scanning calorimeter (DSC), due to the absorption of energy. Typical values of "heat of gelatinization" or "gelatinization enthalpy" are in the range of 8–12 J g^{-1} but are as high as 32 in amylomaize. The loss of crystallinity leads to a rapid swelling of the granule combined with a considerable loss in structure, as seen in a rapid increase in viscosity in a pasting curve (Figure 6). Amylose leaches from the granule but amylopectin remains associated.

Further heating without stirring in an enclosed vessel, such as a DSC, causes dissociation of amylose from lipid. This process also absorbs energy and shows up as an endotherm between 102°C and 110°C.

If, however, the heating is in the presence of stirring in a nonpressurized container, such as a Brabender Viscoamylograph or a Rapid Visco Analyzer (RVA), the viscosity of the suspension continues to increase as the amylose molecules get more dispersed and the granules become more porous, gelatinized, and swollen. Further stirring at a high temperature results in shear thinning, where the molecular entropy is not enhanced but granule structure is gradually further destroyed until a new plateau is reached. This phase is known as "breakdown." As the paste is cooled and stirred, viscosity reaches a final value. The RVA takes ~15 min for the process, instead of about an hour for the Viscoamylograph. Recent models of the RVA have the very significant advantage that they give readings in SI units (cP), in contrast to the arbitrary units of older models and the Viscoamylograph.

In a set of rice starches of equivalent amylose content, most RVA parameters were not significantly affected but breakdown was correlated negatively with the proportion of long amylopectin chains and positively with the proportion of short. In a separate study it was noted that increased firmness of cooked rice was associated with increased content of long amylopectin chains. The short chains are types A and B1, the long B2 to B4. Perhaps the presence of more interconnections between crystalline lamellae, given by a higher content of B3 and B4 chains especially, helps to maintain structure of the gelatinized starch granule. Furthermore, the radius of rotation of the

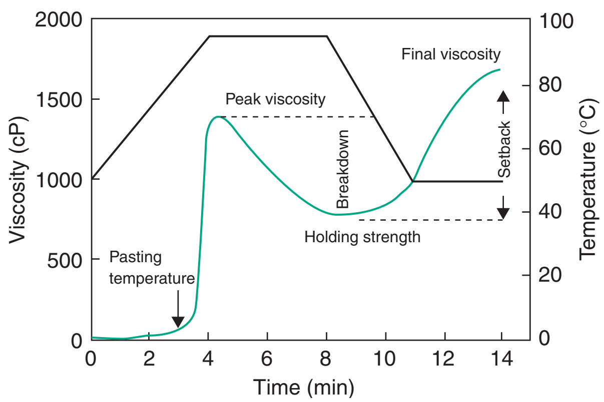

Figure 6 Starch pasting profile, as determined with an RVA (Newport Scientific Pty Ltd., Warriewood, NSW, Australia). Key measurements are named on the graph. Thin line shows temperature profile and thick shows viscosity profile.

chain increases with its degree of polymerization, and the viscosity increases as the cube of the radius, so small increases in chain length can lead to large increases in viscosity.

Reassociation Chemistry

As stated above, the minimum energy state for an α-1,4 linked glucan is as a double helix with another such chain. As a starch solution cools, the chains reassociate in a process termed "retrogradation." Long amylose chains have a considerable radius of rotation and freedom of movement in a solution and may thus entangle with many other long chains at concentrations as low as 1–1.5%. Amylose retrogradation thus entraps a lot of water, involves many molecules, makes a clear hard gel, and is essentially complete when the cooked product has cooled to room temperature. The double helices are generally limited to a few dozen (perhaps 50) glucose residues, leaving great lengths of single helix which can entrap enough iodide ions to give a strong blue color. Amylopectin retrogradation, in contrast, is more likely to involve chains from the same molecule, which are already much shorter than their amylose counterparts. This process can take up to several days and makes a translucent, soft paste. Loss of water from the gel or paste during storage is termed "syneresis."

Some of the components of a retrograded starch are so well crystallized that they are resistant to enzyme attack and are known as "resistant" starch (Table 3). These can contribute to dietary fiber. Recrystallized autoclaved amylomaize starch is sold as resistant starch by at least two manufacturers. Similar material is used as an additive to white bread by an Australian bread manufacturer in order to increase insoluble dietary fiber content without adversely affecting the color or texture of the product.

Mutant Starches

Starch synthesis mutants have been well characterized in several species (*see* **Starch**: Synthesis). These have been valuable not only as industrial and food components but also for elucidating the relative roles of amylose and amylopectin in starch functionality.

GBSS mutants do not synthesize amylose (or do so to only a limited extent) so starch is 100% amylopectin, which is known as "waxy" starch on account of its appearance. These *wx* mutants have long been known in barley, maize, and rice ("glutinous") and have more recently been developed in common wheat and pea. The gel temperature is usually lower and peak viscosity higher in waxy starches than in their normal counterparts. In many cases, final viscosity is higher as well. The isolation of further waxy starches, e.g., from other grain legumes and pseudocereals, may give us even more interesting properties.

High-amylose starches have been harder to develop, even though one has been known for a very long time and was an important part of Mendel's original elucidation of the principles of genetics. The distinction between "round" and "wrinkled" peas, called "rugosus," is now known to be due to a mutation in starch branching enzyme I. The wrinkled phenotype is associated with an amylose concentration of up to 80% in a reduced mass of starch. High-amylose barley (*amo*-1) is 45% amylose, whereas high-amylose maize starch can exceed 85% amylose. Amylose appears to be digested more slowly than amylopectin in the gut of monogastric animals. High-amylose starches have been associated with increased satiety (i.e., reduced desire for food), reduced glycaemic index, and reduced insulin release in comparison with normal-amylose starches. High-amylose foods will thus be an attractive option for people with diabetes and other metabolic problems related to insulin, glycaemia, or obesity.

Many mutations affect maize starch synthesis, including *ae* (amylose extender), *du* (dull), *h* (horny), *sh1* and *sh2* (shrunken), and *su1* and *su2* (sugary). The double mutant *ae wx* maize has no true amylose, owing to the *wx* mutation, but has longer amylopectin chains (average 52 instead of 30 glucose residues) than the wild type due to the *ae* mutation. Starches of other double or triple mutants of maize have desirable properties which emulate or exceed those of chemically modified starches. These include good freeze–thaw stability (*wx sh1*) and low viscosity when hot during processing but high viscosity when cool, which is desirable for canning (*du h, du ae, du su2, ae su2*). Starch of the *ae du wx* triple mutant has high paste viscosity, shear resistance, and acid resistance, and the paste has a creamy texture making it a suitable fat substitute. Chemical analysis of chain length and branching pattern has not yet been at sufficiently high resolution to provide mechanistic

Table 3 Classification of resistant starch

4	Chemically or thermally modified	

explanations of these differences in processing properties.

Conclusions

Numerous techniques have been used to elucidate aspects of the physical and functional chemistry of starch. Although it is a homopolymer consisting entirely of glucose, its structure is extremely variable, showing differences in chain length, branching pattern, and the incorporation of other molecules such as proteins and lipids. These differences lead to a wide range of processing properties. Aspects of the nomenclature may be confusing to the novice, in particular the use of the letters A, B, and C to indicate such diverse traits as different types of amylopectin chain, granule size, or X-ray diffraction pattern. Many questions remain to be answered about the various levels of organization within the starch granule, including the nature of the initiation of the starch granule itself.

Modification

J N BeMiller, Purdue University, West Lafayette, IN, USA

Commercial sources of starches include cereal grains such as corn/maize, wheat, and rice. (Roots and tubers, such as potato, cassava/tapioca, and arrowroot, and the sago palm are other sources.) Corn is by far the principal source of starch, with corn starch making up more than 80% of the world's commercial supply of starch. An additional 8% is obtained from wheat. Most starch used in food or other industrial applications is physically and/or chemically modified in at least one way, and often in multiple ways, before use. Modification is done to enhance the starch's desirable attributes and to minimize its undesirable characteristics. Starch that is to be used in papermaking (the largest industrial use of starch other than that used to produce ethanol of syrups), which utilizes approximately two-thirds of the remaining starch, undergoes modifications different than those to be used in

food applications. Nevertheless, modified food starches exemplify why and how starches are modified.

Background

Food processors generally require starches with better behavioral characteristics than provided by native starches. Cereal starches produce particularly weak-bodied, cohesive, rubbery pastes, and undesirable gels when cooked. However, via modification, the functional properties of starches can be improved. Modification is done to introduce specific functionalities and to make resultant cooked products better able to withstand the conditions of heat, shear, and pH (acid) associated with processing conditions. The final products, modified food starches, are abundant, functional, and useful food ingredients, generally macroingredients.

Modifications can be chemical or physical. Chemical modifications are oxidation, cross-linking, stabilization, and depolymerization. Physical modifications make pregelatinized and cold-water-swelling products. Chemical modifications have the greatest effects on functionalities. Modifications can be single modifications, but modified starches are often prepared by combinations of two, three, and sometimes four processes. Chemical derivatives found in modified food starches (in the USA) are the following:

1. Stabilized starches
   a. hydroxypropyl starches (starch ether);
   b. starch acetates (starch ester); and
   c. starch octenylsuccinates (monostarch ester); and
   d. monostarch phosphate (ester).
2. Cross-linked starches
   a. distarch phosphate and
   b. distarch adipate.
3. Cross-linked and stabilized starches
   a. hydroxypropylated distarch phosphate;
   b. phosphorylated distarch phosphate;
   c. acetylated distarch phosphate; and
   d. acetylated distarch adipate.

Property improvements that can be obtained by chemical modifications include the following:

1. Hypochlorite-oxidized starches
   a. whiter;
   b. lower gelatinization and pasting temperature;
   c. decreased maximum paste viscosity; and
   d. softer, clearer gels.
2. Stabilized (hydroxypropylated or acetylated) starches
   a. lower gelatinization and pasting temperatures;
   b. improved freeze–thaw stability of pastes and gels;
   c. decreased setback of pastes and gels (improved paste stability);
   d. easier redispersibility when pregelatinized; and
   e. greater clarity of pastes and gels.
3. Cross-linked (phosphorylated) starches
   a. increased gelatinization and pasting temperatures;
   b. increased shear resistance;
   c. increased acid stability;
   d. decreased setback of pastes and gels (improved paste stability); and
   e. increased viscosity of pastes.
4. Cross-linked and stabilized starches;
   a. lower gelatinization and pasting temperatures, but increased paste viscosity and
   b. other attributes of stabilized and cross-linked products.
5. Thinned (depolymerized) starches
   a. decreased viscosity of pastes;
   b. lower gelatinization and pasting temperatures; and
   c. increased solubility.

Any starch (corn, potato, tapioca/cassava, wheat, rice, etc.) can be modified, but modification is practiced significantly only on corn (both common corn and waxy maize) and potato starches and, to a much lesser extent, on tapioca and wheat starches. This article is written primarily from the point of view of corn and waxy maize starches.

Methods of Production and Applications

Cross-linked and/or stabilized starch products are prepared by chemical derivatization of a starch, most often in an aqueous slurry in a batch process. In such a process, a slurry of 30–45% solids (starch) as obtained from the mill is introduced into a stirred reaction tank. Sodium chloride or sodium sulfate is added to inhibit granule swelling. The pH is adjusted with sodium hydroxide (up to values of $\sim$11.5, depending on the reaction). Chemical reagents are added. Temperature is controlled. Reactions may be done at temperatures up to 50°C, but gelatinization must be avoided to allow recovery of the modified starch in granule form by filtration or centrifugation. Because the gelatinization temperature may be lowered by the modification, there may be, and often is, a limit to the degree of substitution that can be made in this manner. (The degree of substitution is the average number of hydroxyl groups per α-D-glucopyranosyl unit (the monomeric unit of starch) that have been derivatized, the maximum

being 3.) In some reactions, the pH needs to be controlled by the metered addition of dilute sodium hydroxide solutions. Following modification to the desired level, the starch is recovered by centrifugation or filtration, washed, and dried.

Chemical reactions currently both allowed and used to prepare modified food starches in the USA are as follows:

- esterification with acetic anhydride, succinic anhydride, the mixed anhydride of acetic and adipic acids, 1-octenylsuccinic anhydride, phosphoryl chloride, sodium trimetaphosphate, sodium tripolyphosphate, or monosodium orthophosphate;
- etherification with propylene oxide;
- acid modification with hydrochloric or sulfuric acids;
- bleaching with hydrogen peroxide, peracetic acid, potassium permanganate, or sodium hypochlorite;
- oxidation with sodium hypochlorite; and
- various combinations of these reactions.

Other reagents may be used in other countries.

Waxy maize starch modifications are especially popular in the US food industry because the inherent properties of waxy maize starch are preferred over modifications to common corn starch.

Cross-Linking

Cross-linking is the most important modification of a food starch. Cross-linking occurs when starch granules are reacted with difunctional reagents to connect hydroxyl groups on two different molecules within the granule. Cross-links reinforce the granule and reduce both the rate and the degree of granule swelling and subsequent disintegration, i.e., reduce sensitivity to processing conditions (high temperature; extended cooking times; low pH; high shear during mixing, milling, homogenization, and/or pumping). Cooked pastes of cross-linked starches are more viscous, heavier-bodied, shorter-textured, and less likely to break down with extended cooking times, greater acidity, or severe agitation than are pastes of the native starches from which they are prepared. Only a small amount of cross-linking is required to produce a noticeable effect; for example, one cross-link for every approximately 1200 α-D-glucopyranosyl units greatly reduces both the rate and the degree of granule swelling, greatly increases paste stability, and changes dramatically both the viscosity profile as the starch is cooked and the textural characteristics of its paste. Three times that much cross-linking, for example, produces a product in which granule swelling is restricted to the point that a peak viscosity is never reached in a slurry heated to 95°C and held at that temperature with moderate stirring. As the number of cross-links increases, the granules become more and more tolerant to physical conditions and acidity, and swell and disintegrate (solubilize) upon cooking less and less. Energy requirements to reach maximum swelling and viscosity are also increased.

By far the most common cross-links are distarch phosphate esters. These distarch phosphates are prepared with either phosphoryl chloride or sodium trimetaphosphate. Phosphoryl chloride is very reactive and undoubtedly reacts near granule surfaces. To prepare cross-linked starches with phosphoryl chloride, the reagent is added to an aqueous starch suspension of pH 8–12. To cross-link a starch with sodium trimetaphosphate, it is slurried in a solution of the reagent at pH 5.0–8.5; the suspension is filtered, and the starch is dried. In this case, the cross-links are undoubtedly more evenly distributed throughout the granule.

A relatively small amount of cross-linked starch is made by reaction of corn starch with the mixed anhydride of adipic and acetic acids in aqueous alkaline suspension.

Stabilization

Derivatization of a starch with monofunctional reagents reduces the intermolecular associations which result in gelation of its paste and/or precipitation of the starch polymers (combined processes termed retrogradation or setback). Pastes of unmodified starches generally will gel, and the gels will usually be cohesive, rubbery, long-textured, and prone to syneresis. (Waxy maize starch pastes gel to a very limited extent at room temperature, but will become cloudy and chunky and exhibit syneresis when stored under freezing conditions.)

The most common derivatives employed for starch stabilization are the hydroxypropyl ether and acetate and monostarch phosphate esters. Acetylation is accomplished by treating a starch slurry with acetic anhydride at pH 7–11, the optimum pH depending on the reaction temperature. Acetylation of starch lowers the gelatinization temperature, an indication of a weakening of granules. Upon cooking, a higher peak viscosity is obtained due to greater granule swelling. Upon cooling of the resulting paste, the viscosity becomes lower than that obtained from the unmodified starch, an indication of improved stability, i.e., less retrogradation. Acetylated starches with an acetyl content of up to 2.5% (degree of substitution, DS, 0.09) can be used in food products (USA). (A DS of 0.09 indicates an average of nine acetyl goups per 100 α-D-glucopyranosyl units.)

Sodium phosphate monoesters are prepared by impregnating the starch with a solution of sodium tripolyphosphate. After adjustment of the pH to 5.0–8.5, the slurry is mixed, then filtered, and the filter cake is dried and heated. Sodium tripolyphosphate is used to make products of up to 0.002 DS (one phosphate group per 500 α-D-glucopyranosyl units), the maximum allowed in the USA. Monosodium orthophosphate in the pH range 5.0–6.5 is also used to produce monostarch phosphates in the same way.

Monostarch phosphates produce stable pastes that are clear and have a long, cohesive texture. Paste viscosity can be controlled by varying the concentrations of phosphate salt, time of reaction, temperature, and pH. Increasing substitution lowers the gelatinization temperature; products become cold-water-swelling at DS 0.07. Corn starch phosphates of DS 0.01–0.03 produce pastes with hot viscosity, clarity, stability, and texture more like those of potato starch. Starch phosphates are good emulsion stabilizers and produce pastes with improved freeze–thaw stability.

Hydroxypropyl ether derivatives of starches are prepared by reacting an alkaline slurry with propylene oxide. To the starch slurry is added sodium sulfate and sodium hydroxide. The reactor is charged with propylene oxide and sealed. Reaction is continued for ~24 h at ~49°C. The maximum allowable moles of substitution in the USA is 0.2 (7.0% of hydroxypropyl groups). (Moles of substitution, MS, is essentially the same as DS but is used in place of DS because each hydroxypropyl group contains a hydroxyl group that can itself be etherified, so that the maximum number of substituent groups per glucosyl unit can be more than 3.)

Low-MS hydroxylpropylstarches behave much like low-DS starch acetates and are used because of similar improvements in texture and appearance. The hydroxypropyl ether linkage is, however, much more stable than an ester linkage.

Starch succinate half-esters are prepared by reacting starch with succinic anhydride.

Starches with Hydrophobic Groups

Reaction of starch with 1-octenylsuccinic anhydride introduces hydrophobic substituent groups. Such derivatives can be used as emulsifiers and emulsion stabilizers in products based on oil-in-water emulsions, such as pourable dressings and flavored beverages. Flavor oil emulsions containing a thin-boiling starch or dextrin (see below) derivatized with 1-octenylsuccinate ester groups may be spray-dried. The flavor oil in the resulting powder is protected against oxidation, and the emulsion will reform when the powder is stirred into an aqueous medium. Gum arabic is, however, usually the material of choice for this application. Higher-DS products are nonwetting and are used as release agents for dusting on dough sheets and as processing aids. The maximum DS level allowed in the USA is 0.02.

Acid Modification

Thin-boiling starches are prepared by treating a suspension of a native or derivatized starch with dilute mineral acid at a temperature below the gelatinization temperature. When a product that gives the desired paste viscosity is produced, the acid is neutralized, and the product is recovered by centrifugation or filtration, washed, and dried. Even though only a few glycosidic bonds are hydrolyzed, granules disintegrate more easily and after only a small degree of swelling. Acid-modified starches form gels with improved clarity and increased strength, even though their pastes are less viscous. Thin-boiling starches are used as film formers and adhesives in products such as pan-coated nuts and candies, whenever a strong gel is desired, e.g., in gum candies such as jelly beans, jujubes, orange slices, and spearmint leaves, and in processed cheese loaves. To prepare especially strong and fast-setting gels, a high-amylose corn starch is used. More extensive modification with acid produces dextrins.

Oxidation

Depolymerization, viscosity reduction, and decreased pasting temperature can also be achieved by oxidation with sodium hypochlorite (chlorine in an alkaline solution). Oxidation also reduces association of amylose molecules, i.e., results in some stabilization via introduction of small amounts of carboxylate and carbonyl groups. Oxidized starches produce intermediate-viscosity and soft gels and are used when these properties are needed. They are also used to improve adhesion of starch batters to fish and meat and in breadings. Mild treatment with sodium hypochlorite, hydrogen peroxide, or potassium permanganate simply bleaches the starch and reduces the count of viable microbes.

Pregelatinization

Pregelatinized starches are precooked starches that can be dispersed (dissolved) in water at temperatures below the gelatinization temperatures of the parent starches; thus, these "instant" starches need no cooking. To prepare a pregelatinized starch, a slurry is simultaneously cooked and dried on hot drums. Because pregelatinized starch products are powders prepared from dried pastes, generally no granules are

present, although granule fragments may be. Both chemically modified and unmodified starches can be used. The resulting products contain no intact starch granules. If chemically modified starches are used, the properties introduced by the modification(s) are found in the pregelatinized products; thus, paste properties, such as freeze–thaw stability, can be characteristics of pregelatinized starches. Several physical forms of pregelatinized starches are produced. For example, some will produce smooth solutions; others will produce pulpy or grainy dispersions and find use in fruit drinks and tomato products. Pregelatinized starches are often used in dry mixes, as are maltodextrins, because they disperse readily, even when mixed with other ingredients. Starches that are not pregelatinized are known as cook-up starches.

Cold-Water-Swelling Starches

Starch products that are gelatinized starches, i.e., starches that have lost their crystallinity, but which retain their granular form, in contrast to standard pregelatinized starches, are called cold-water-swelling starches. There are several ways that such products can be prepared; one way is to heat a starch in an aqueous alcohol solution with sufficient water to allow gelatinization and sufficient alcohol that granule integrity is maintained. Cold-water-swelling products swell rapidly and thicken unheated aqueous systems. (A granular, cook-up starch requires heating a slurry to the pasting temperature before thickening occurs.)

Multiple Modifications

Modified food starches are tailor-made for specific applications. Most modified food starches are made by cross-linking, introduction of monosubstituent groups (stabilization), or a combination of these two approaches. Many products, in fact, have received two or more modifications. For example, a modified food starch may be a cross-linked and stabilized waxy maize starch; another may be a stabilized, acid-thinned, and pregelatinized common corn starch. Characteristics that can be controlled/improved by multiple modifications include, but are not limited to, one or more of the following:

- adhesion,
- clarity of solutions/pastes,
- color,
- emulsion stabilization,
- film formation,
- flavor release,
- hydration rate,
- moisture retention and control in product,
- mouth feel of product,
- oil migration control in product,
- paste texture/consistency,
- product form (liquid, semisolid, solid),
- sheen of product,
- shelf-stability of product,
- stability to acids,
- stability to heat,
- stability to shear,
- tackiness,
- temperature required to cook, and
- viscosity (hot paste and cold paste).

Digestion and Metabolism

Various regulations concerning reagents that may be used and the maximum allowable modification of a starch for food use, alone or in combination with another modification, are in effect around the world. Generally, the level of substitution in a derivatized food starch is below DS 0.1 and in the range DS 0.002–0.2. Because of this low level of modification, the digestion, metabolism, and caloric values of modified food starches are reduced only to a minor, usually unmeasurable, extent as compared to native starches. Because only monosaccharides (D-glucose in this case) are absorbed, fragments containing esterified, etherified, or oxidized α-D-glucopyranosyl units should not be absorbed from the small intestine.

Introduction

Starch makes up by far the largest component of cereal grains and is also found in fruits, roots, tubers, and leaves. It is a very important source of energy in our diets. Most starch is easily digested; however, some starches termed resistant starch are digested only after they reach the large intestine and recent research shows that this type of starch has positive attributes for bowel health. Starch also performs two basic roles in the food industry, as a stabilizer providing viscosity, texture, mouth feel, and consistency to food products and as a processing aid to facilitate manufacturing. As a consequence of its low cost and diverse functionality, starch is used in a range of food and nonfood industries.

Starch is a polymer of glucose monomers linked by α-1,4 and α-1,6 linkages, so it is a glucan. Cellulose is also a glucan; however, the single type of glucose linkage between the glucose molecules (β-1,4) provides very different properties. In starch the frequency of α-1,6 linkages defines the two major components of starch – amylose and amylopectin. Amylose and amylopectin differ in their degree of polymerization (DP) or number of glucose residues and branching frequency. Amylose is mainly linear with $<1\%$ α-1,6 linkages and a DP of 500–5000, whereas amylopectin is highly branched with 4–6% α-1,6 linkages and a DP of 50 000–500 000. The ratio of amylose to amylopectin and the details of the branching (such as the length of the branches and distance between branches) are important determinants of the suitability of starch for specific end uses. Generally, the amylose content of starch is $\sim$25%, but it can vary from 0% to 80% depending on alterations in the starch biosynthetic pathway.

In nature starch is found in granules. X-ray diffraction studies have revealed a semicrystalline structure for such granules. The X-ray diffraction pattern is determined by the proportion of the external chains that are aligned in crystalline arrays and by the packing in the array. Amylopectin molecules are radially arranged with their nonreducing ends pointing towards the surface. Starch is packaged into alternating crystalline and amorphous lamellae. The location of amylose chains within this structure is unclear and it has been suggested that it is present in the amorphous cavity and/or interspersed in the amylopectin crystalline region.

Starch is synthesized in plants within organelles that are either photosynthetic (such as the chloroplast of leaf cells) or nonphotosynthetic, such as the amyloplast of cereal endosperm cells. The starch in chloroplasts is synthesized during the day and broken down at night and it is often termed transitory starch. In contrast, the starch synthesized in seeds is broken down only on germination and the starch is termed reserve starch. There are some differences in the detail of biosynthesis between the two types of starch. This article is mainly concerned with the starch deposition within the nonphotosynthetic amyloplast.

Starch from Different Cereals

Starch granules in the reserve tissues vary widely in size distribution and shape between species (see Table 1 and Figure 1). Maize and rice starches exhibit a unimodal granule size distribution ranging from 5 to 20 μm for maize and 2 to 5 μm for rice. Starches of wheat, barley, and rye are characterized by a bimodal distribution composed of an A granule population of 10–35 μm diameter which are lenticular in shape with a characteristic equatorial groove and a B granule population of generally spherical granules with a diameter less than 10 μm. In barley, a trimodal distribution of starch granules with "C" granules of diameter less than 5 μm is also reported. In wheat, the larger granules, which are initiated during the early stages of endosperm development, constitute 70–80% of the starch by weight and the more numerous smaller granules, which are started later, contain only 20–30% of the total starch in grain. There have been some reports of slight variation in amylose content between the A and B granules and between different regions of the granule.

Table 1 Typical properties of starch from different sources

Source	*Starch granule size range (μm)*	*Starch granule size distribution*	*Apparent amylose content*	*Gelatinization onset temperature[a] (°C)*
Wheat	3–35	Bimodal	25	57
Barley	2–35	Trimodal	22	56
Rice	2–5	Normal	18	70
Maize	5–20	Normal	28	64

[a] Gelatinization temperature measured by differential scanning calorimetry using starch mixed with water in a ratio of 2 parts of water : 1 part of starch. The heating rate was 10°C min^{-1} over a temperature range of 25–150°C. Data compiled from Jane J, Chen YY, Lee LF, *et al.* (1999) Effects of amylopectin branch chain length and amylose content on the gelatinization and pasting properties of starch. *Cereal Chemistry* 76: 629–637; and Rahman S, Li Z, Batey I, Cochrane MP, Appels R, and Morell M (2000) Genetic alteration of starch functionality in wheat. *Journal of Cereal Science* 31: 91–110.

The amylose/amylopectin ratio does not normally vary greatly between sources, with a ratio of 1 : 3 being common. However, mutations where amylose is completely missing are fairly common and such starches are known as waxy starches. In some food preparations such starches are preferred, e.g., in the preparation of many Asian sticky rice desserts. Waxy starches are also often preferred as thickeners because of the greater solubility of starches without amylose. High amylose starches are best known in maize among cereals. Here the amylose content is ~80% and the starch granules appear to be distorted. High amylose starches are in demand because such starches are useful starting points for the production of resistant starches in foods and can be used in packaging materials and adhesives.

An important property of starch granules is the gelatinization onset temperature, the temperature at which the granules begin to lose internal order and crystallinity. The gelatinization temperature of starches can vary considerably, from ~57°C for barley starches to over 75°C for rice. Waxy starches appear to have slightly lower gelatinization temperatures. The differences in gelatinization correlate with differences in the branch lengths of starches from different sources and in the packaging of branches in the granule. Another important property is the viscosity of the gelatinized starch.

A principal difference between starches from cereals and tubers is in the proportion of phosphate groups found in the starch. Potato has ~0.5% phosphorylated glucose residues compared to ~0.05% for cereal starches. Usually the phosphate is linked to carbon 6 of glucose molecule. The difference in the phosphorylation imparts tuber starches with properties significantly different to cereal starches in terms of viscosity and flow properties.

The lipid content of cereal starches is low, ~1%. However, even this can be divided into three operational classes: nonstarch, surface, and internal lipids. The internal lipids of wheat consist entirely of lysophospholipids which are complexed inside linear glucan chains. The fatty acid composition of lipids differs slightly between wheat and rice, with wheat being richer in 18:2 (linoleic acid) and rice having more 16:0 (palmitic acid) fatty acids. How lipids accumulate in cereal starches is not yet clear but the hydrophobic environment in the interior of the glucan chain leads to complexes of lipids with amylose.

Pathway from Sucrose to Starch Granule

Pathway Preceding Starch Biosynthesis

Starch synthesis requires a hexose phosphate supply. Plants produce sugars in photosynthetic tissue (e.g.,

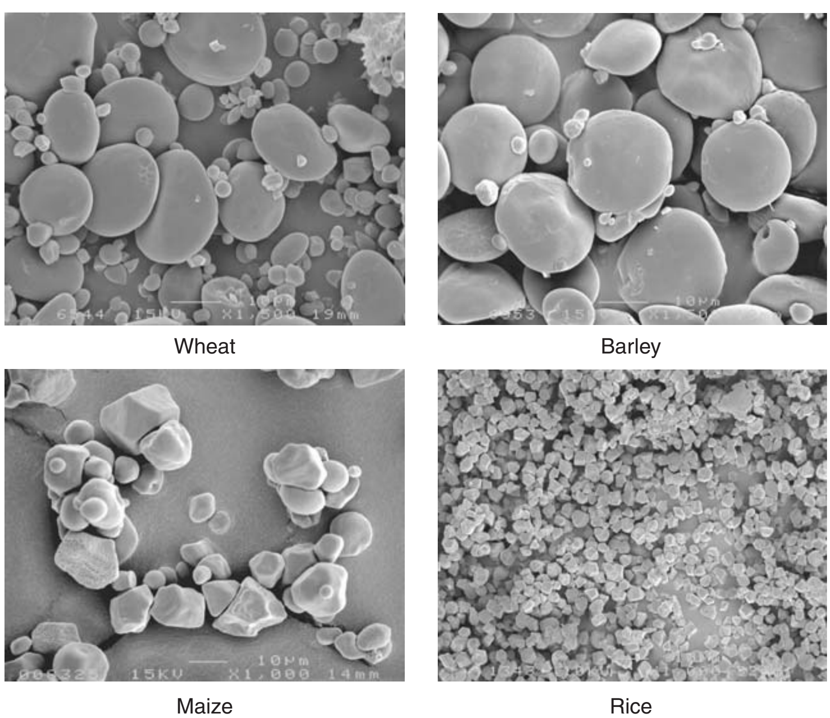

Figure 1 Starch granules from common cereals. (Scanning electron micrographs by CSIRO Plant Industry by scanning electron microscopy.)

leaves, pericarp of the grain) where they can support leaf starch synthesis. In the endosperm, incoming sucrose is either converted into uridine diphosphate (UDP)-glucose and fructose by a UDP-dependent sucrose synthase or converted to hexoses by invertase, as observed in maize. The UDP-glucose or hexose phosphate derived from fructose is inter-converted to glucose-1-phosphate by other enzymes such as UDP-glucose pyrophosphorylase, hexokinase, and phosphoglucomutase. This glucose-1-phosphate can be used in various metabolic pathways; however, once the glucose-1-phosphate is utilized to form adenosine diphosphate (ADP)-glucose (ADPG), a commitment is made to the synthesis of starch.

Biochemistry of Starch Biosynthesis

A consensus view of starch biosynthesis in cereal endosperm is shown in Figure 2. Starch biosynthesis requires four types of enzymes, which are as follows.

1. ADPG pyrophosphorylase which produces ADP-glucose from glucose-1-phosphate and ATP.
2. Starch synthases which elongate glucan chains by using ADP-glucose to add a glucose residue at the nonreducing end.
3. Starch branching enzymes which introduce α-1,6 branches to the glucan chain. These branches can then be extended by starch synthases.
4. De-branching enzymes remove branches from starch molecules. The role of de-branching enzymes in starch synthesis is still being debated, although the genetic evidence for a role for these enzymes is unambiguous.

Other enzymes are also capable of influencing the properties of the starch produced and these will be discussed later.

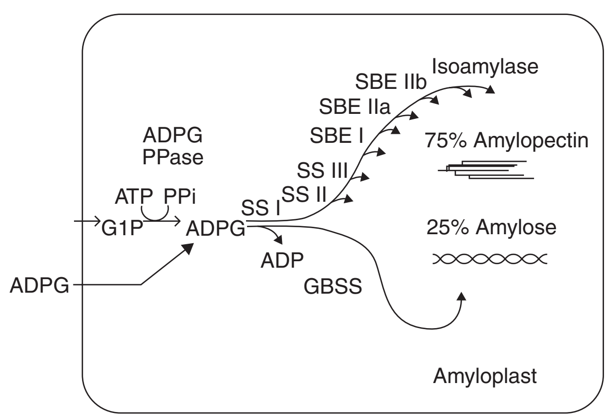

Figure 2 A consensus view of starch biosynthetic pathway in cereals.

Maize has been the most extensively characterized model system for the isolation of mutations affecting starch biosynthesis. Analysis of these mutants (along with those from other model systems such as Arabidopsis) has greatly contributed to the exploration of the key enzymes and their isoforms involved in starch biosynthesis. In maize, mutations in genes affecting starch synthesis such as the waxy and amylose extender mutations are brought about by the insertion of transposable elements, a DNA sequence capable of moving from one location to another within a genome. Such mutations often lead to alterations in the structure and properties of starch. Specialty maize varieties such as waxy (granule bound starch synthase 1 mutant), amylose extender (starch branching enzyme IIb mutant), sugary 2 (starch synthase IIa mutant), sweet corn (sugary-1, isoamylase mutant), and dull (starch synthase III mutant) find applications for specific food and industrial use.

ADPG Pyrophosphorylase

ADPG pyrophosphorylase is believed to be the key enzyme which determines the rate of starch synthesis in leaves. Genetic engineering has been used to introduce the ADPG pyrophosphorylase from *Escherichia coli* (which is not subjected to feedback inhibition) into potatoes, and tubers with a higher content of starch were obtained. It is not clear, however, whether ADPG pyrophosphorylase is also the rate-limiting enzyme for starch biosynthesis in the grain as the purified enzyme from leaves and grains show differences in properties.

ADPG pyrophosphorylase from both leaves and endosperm is composed of four subunits, two of each type, large and small. The large subunit has a mass of ~55 kDa, whereas the small subunit is slightly smaller, ~50 kDa. The sequence of amino acids of these subunits is ~50% identical. Mutations in the sequence of either of these subunits can destroy or reduce the activity of the enzyme and then grains or seeds with a shrunken appearance (due to decrease in starch synthesis) are produced. Such mutations in ADPG pyrophosphorylase were given the names brittle-2 (mutation in small subunit) and shrunken-2 (mutation in large subunit) when they were discovered in maize (Table 1).

Recent evidence shows that ADPG pyrophosphorylase in the cereal grain exists both in the cytoplasm and amyloplast of endosperm cells; however, most of it is in the cytoplasm. This enzyme in the cereal grain differs from that in the seeds of dicots and leaves of all the plants investigated so far, where ADPG pyrophosphorylase appears to exist exclusively in the plastids. Evidence from both monocots (such as barley and

maize) and dicots (such as peas) suggests that there is more than one gene for the large and small subunits of ADPG pyrophosphorylase and different versions of these may code for the forms that are expressed in the cytoplasm and in the plastid.

The transfer of ADP-glucose from the cytoplasm of endosperm cells to the amyloplast is important as the other enzymes in the process are located there. Mutations are known where this transfer is affected and this too produces grain where starch synthesis is affected (Table 2).

ADPG pyrophosphorylases exhibit complex regulatory properties which vary depending on the species and tissue source. The enzyme from the leaves of all plants examined, maize endosperm, and potato tubers are allosterically activated by 3-phosphoglyceric acid (3-PGA) and inhibited by inorganic phosphate. Pea and bean embryo, and wheat and barley endosperm ADPG pyrophosphorylases, on the other hand, are much less sensitive, or insensitive, to modulators compared to their leaf counterparts. The allosteric properties of ADPG pyrophosphorylases are of potential importance in determining its role in controlling the rate of starch synthesis. Altered starch biosynthetic rates resulting from altered allosteric properties due to mutations in ADPG pyrophosphorylase subunits are demonstrated in maize and the green algae, Chlamydomonas.

Table 2 List of selected starch mutants[a]

Mutant	*Phenotype*	*Plant species*	*Causal mutations/only enzyme affected*
Brittle-1 (bt 1)	Low starch	Maize	Adenylate transporter
Shrunken-1 (sh 1)	Low starch	Maize	Sucrose synthase
Rugosus 4 (rug 4)	Low starch	Pea	Sucrose synthase
Rugosus 3 (rug 3)	No starch	Pea	Phosphoglucomutase
Rb	Decreased starch content and increased levels of sucrose	Pea	ADPG pyrophosphorylase
Brittle-2 (bt 2)	Low starch	Maize	Small subunit of ADPG pyrophosphorylase
Shrunken-2 (sh 2)	High levels of sucrose and low levels of starch	Maize	Large subunit of ADPG pyrophosphorylase
Waxy (wx)	Zero amylose	Maize, wheat	GBSS 1
Low amylose (lam)	Low level of amylose	Pea	GBSS
Shrunken (shx)	Reduced starch content, altered granule size distribution	Barley	SS-I (not known to be casual)
Sugary-2 (su 2)	Altered granules, high sugar	Maize	Starch synthase IIa (?)
Rugosus 5 (rug 5)	Granules with deeply divided lobes, reduced amylopectin synthesis, altered amylopectin chain length	Pea	SS II
Dull (du1)	Mature kernels with tarnished, glassy and dull appearance. High apparent amylose content	Maize	Mutation at SS III, SBE IIa affected secondarily
Amylose extender (ae)	High levels of amylose	Maize, rice	SBE IIb, RBE III
High amylose (amo1)	Higher level of amylose	Barley	Unknown
Floury-2 (flo 2)	Soft, white endosperm which crumbles easily into powder. High amylose content	Rice	RBE I RBE III, and GBSS (not known to be casual)
SbeIIa::mu	No endosperm phenotype, altered leaf starch	Maize	BE IIa
Sbe1::mu	No known phenotype	Maize	BE I
Rugosus (r)	Wrinkled seed, lowered starch, enhanced amylose, sucrose and lipid levels	Pea	SBE I
Sugary-1 (su 1)	Low starch, phytoglycogen accumulation	Maize, rice	Isoamylase
Soft starch (h)	Loosely packed, large granules	Maize	Unknown
SGP-1	Abnormal starch granule morphology. High amylose content	Wheat	SS II
Isoamylase mutant	Phytoglycogen accumulation. No B granule initiation	Barley	Isoamylase
Sex6	Decreased amylopectin synthesis, shortened amylopectin chain length distribution, reduced gelatinisation temperature	Barley	SS IIa

[a] Data compiled from the references in "Further Reading" section.

Starch Synthases

Starch synthases elongate pre-existing glucan chains in the amyloplast by adding the glucosyl moiety from ADP-glucose to the nonreducing end of an existing α-1,4 glucan.

Two classes of starch synthases have been identified in plants. One class of starch synthase is only found bound to starch granules and these are known as granule-bound starch synthase (GBSS). The other class of starch synthase is present either in the amyloplast stroma alone or distributed between the stroma and granular fraction and these are known as soluble starch synthases. Four types of soluble starch synthase (SS) have been reported in crop plants: SS I, SS II, SS III, and SS IV. In monocots the SS II has been further subdivided into the IIa and IIb forms. The primary structures of soluble starch synthases from different sources share a distinguishing feature, an N-terminal extension with little homology between sequences from different sources. Comparison of the deduced amino acid sequences of starch synthases revealed that maize SS I, SS IIa, and SS IIb contained an N-terminal extension of 93, 176, and 144 amino acids, respectively, compared to GBSS. Pea SS II also contains a “flexible” 162 amino acid N-terminal arm. It has been shown through expression analysis using N-terminally truncated SS II that the N-terminal extension is not essential for the catalytic activity of the enzyme but is probably related to substrate binding.

There are two types of GBSSs, I and II. GBSS II is similar in amino acid sequence to GBSS I but is not expressed in the grain. GBSS I is a single polypeptide, ~60 kDa in mass. If the grain lacks an active GBSS I, then starch is composed almost entirely of amylopectin. Such starch is called waxy starch (Table 2). Clearly then GBSS I is essential for the synthesis of amylose and the other starch synthases cannot substitute for it. The hexaploid nature of wheat allows a range of starches of intermediate amylose content to be developed, an opportunity not possible in diploids such as barley. In wheat the GBSS I gene has been mapped as a triplicate set of single-copy homoeoloci on chromosome arms 7AS, 4AS, and 7DS. A reduction in the proportion of amylose is observed when the GBSS I activity is reduced and these starches are known as low amylose or partial waxy starches. The loss of only one of the three isoforms, the 4A form of GBSS, has clearly been shown to yield a starch with increased ability to swell in water on heating. This property is desirable for Udon noodle production and such low amylose starches from wheat are preferred for this end use.

The soluble starch synthases are also all single polypeptide enzymes. SS I is ~75 kDa in mass and is found both free in the amyloplast and bound to the starch granule. The importance of this enzyme is not clear as no mutants have been discovered which lack this enzyme. This may mean that either the lack of this enzyme has no effect on starch synthesis in the grain or that it is so important that no grain forms. Further research is needed in this area.

SS II has been subdivided into IIa and IIb forms on the basis of gene sequence comparisons; however, the IIb form does not seem to be present as an expressed protein in the cereal endosperm. The IIa form is ~85 kDa in mass although the wheat enzyme appears to be over 100 kDa by electrophoresis. Barley and wheat lines lacking SS IIa have been produced and the starch from these lines is clearly different from normal. The barley mutants have high amylose (70%); the wheat mutants less so (35%). It is not clear if there are differences in the structure of the amylose. The starch granules are of distorted appearance and have a lower gelatinization temperature. The proportion of branches of 7–25 glucose units in length is decreased and the proportion of branches of 4–6 glucose units in length is increased. There are also effects on the abundance of other starch biosynthetic enzymes so it is difficult to know how many of the effects on starch properties are the direct result of the lack of this enzyme and how many are due to the other enzymes affected. The differences in the starch between indica and japonica rice cultivars appear to be due to a combination of alterations in SS IIa and GBSS.

SS III is a polypeptide of ~180 kDa in length. The absence of this enzyme in maize leads to a slightly higher amylose content and the starch looks dull compared to normal. An intermediate glucan fraction (~15%), which is distinguished from amylose and amylopectin, occurs in starch from maize lines missing SS III.

The importance of SS IV for starch synthesis in the endosperm is at present unknown.

Starch Branching Enzymes

Starch branching enzymes (SBEs), as their name suggests, are required for the addition of branches to linear glucans. Their impact is clearly more on the synthesis of amylopectin than amylose, although branching enzymes may also have a subtle role in amylose synthesis.

There are two broad types of SBEs: SBE I and SBE II. Expression of these enzymes in bacteria has shown that SBE I adds longer branches than SBE II. They are both single polypeptide chains of ~85 kDa. SBE I and SBE II share ~60% sequence identity over the middle third of the molecules.

The importance of SBE I for starch biosynthesis in the grain is not clear. A mutation in SBE I in maize did not produce a clear phenotype. A number of isoforms of SBE I may exist in wheat.

SBE II is divided into two isoforms in cereals: IIa and IIb. The amino acid sequences of IIa and IIb isoforms are very similar (over 80% identity within a species). In maize the IIb form makes up ~90% of the starch branching II activity in the endosperm but the proportion of the two isoforms is nearly equal in wheat. Maize lines lacking branching enzyme IIb produce a very high (70% and higher) proportion of amylose. Such high amylose starches are linked to the formation of resistant starches in products. Resistant starch has been shown to have very beneficial effects if present in the diet. In contrast, the role of branching enzyme IIa in the cereal endosperm is not clear and may vary from cereal to cereal.

De-branching Enzymes

De-branching enzymes remove branches from branched glucans. Two types of de-branching activities, pullulanase and isoamylase, have been described from developing endosperm of rice and maize. The role and importance of these enzymes for starch biosynthesis is still being debated.

Pullulanase is a single polypeptide enzyme of ~100 kDa in mass. No mutants are known in which only pullulanase is affected and the role of this enzyme in starch biosynthesis is still to be determined.

Isoamylase is also a single polypeptide enzyme of ~90 kDa in mass. It can de-branch highly branched structures like amylopectin and glycogen. The lack of this enzyme in rice and maize is associated with the production of a very highly branched and unusual polysaccharide called phytoglycogen. Such lines also contain high levels of free sugars and are known as sugary mutants. However, there is also a reduction in the level of pullulanase in these sugary mutants so it is difficult to know which of the effects are directly due to the lack of isoamylase.

There are differences between the isoamylase mutants described in rice, maize, and barley. In rice, different phenotypes were observed for the sugary mutants ranging from no starch and only phytoglycogen to starch in the outer layer of the endosperm and phytoglycogen internally. In contrast in barley, both phytoglycogen and starch were reported in the same endosperm cells. The maize sugary mutants also contain both phytoglycogen and starch. In barley it has been reported that the lack of isoamylase leads to an alteration in the initiation pattern of starch granules.

While it is established that isoamylase plays a significant role in starch biosynthesis, the mechanism by which it acts is not resolved. Two mechanisms have been proposed. One proposal known as the "glucan trimming" mechanism suggests that isoamylase removes moderately and loosely spaced branches from a soluble pre-amylopectin structure that interfere with crystallization of amylopectin, and promotes the formation of stable amylopectin structure with regularly packed glucose units. In the absence of isoamylase activity, the pre-amylopectin structure is further branched by branching enzymes and results in the production of phytoglycogen. The second model is based on the assumption that a competition exists between polysaccharide aggregation into starch and the nonproductive formation of water-soluble polysaccharides (WSPs), in turn resulting in a competition for both carbon source and for soluble enzymes involved in amylopectin synthesis. The role of isoamylase here would be to clear the stroma of WSP and prevent phytoglycogen formation. A role in starch granule initiation and growth, apart from phytoglycogen suppression, for isoamylase is also suggested based on analysis of barley isoamylase mutants.

Other Enzymes with Potential Roles in Synthesis

Much of the new insights into starch synthesis has come from the study of simpler systems, such as Chlamydomonas and Arabidopsis. Such studies have indicated other loci that are important in starch synthesis in these organisms. It is possible (although by no means certain) that genes encoded by such loci are also important for starch synthesis in the grains of cereals.

D-enzyme or disproportionating enzyme has the property of breaking a glucan chain and adding one portion to the nonreducing end of a pre-existing chain. In this way one chain is made shorter but the other one is made longer. In Chlamydomonas mutants where the gene for D-enzyme is affected, the starch produced appears to have somewhat more amylose. These mutants are required to be grown in constant light. Genes for D-enzyme have been described from Arabidopsis and rice, but the importance of D-enzyme to starch biosynthesis in the cereal grain is yet to be clarified.

Starch phosphorylase is another enzyme that could have an impact on starch biosynthesis in the grain. This enzyme breaks down starch and was originally considered to be important for degradation. There are at least two isoforms in the plant – a cytosolic form

and a plastidic form; however, Chlamydomonas appears to contain three isoforms. Lack of one of these isoforms leads to a starch excess phenotype and the production of larger starch granules but the evidence for cereals is yet to be presented.

The initiator protein for glycogen is called glycogenin. Glycogenin is an autocatalytic glycoprotein and the glucose residues provide the starting point for glycogen synthesis. By analogy with this a number of glycogenin-like proteins have been described from plants but again, the importance of these proteins to starch biosynthesis in the grain is yet to be elucidated.

The R1 protein is important for starch phosphorylation in potatoes. If this protein is down-regulated in potatoes, then the starch produced is sharply reduced in the phosphate content and increased in amylose content. The peak viscosity was also reduced. As cereal starch contains naturally far less phosphate, the importance of this protein for cereal starch biosynthesis needs to be ascertained. However, sequences similar to the gene for R1 protein are found in the cereal genome. In Arabidopsis and potato, absence of the R1 protein leads to a decrease in starch breakdown and the consequent production of the starch excess phenotype.

Genes and Genetics in Wheat

The structure of the genes for the principal starch biosynthetic enzymes mentioned above has been described from wheat (Figure 3). The genes are all complex in intron/exon structure. The genes differ considerably in length, varying from 6 to 11 kb.

The processing of the initial transcript to the final RNA is clearly a complex process. Many of the mutants in GBSS I are due to errors or inefficiencies in the processing of the RNA. In barley, the waxy mutations have been reported that produce low amylose rather than zero amylose. In these mutant starch granules, the outer cell layers of the endosperm contain more amylose than the inner layers. Investigation of these mutants revealed that the change in expression of GBSS I in these lines is due to a 413 bp deletion of part of the promoter and 5′ untranslated region of the gene. Two other barley waxy families analyzed have no detectable level of amylose – due to a 1 bp alteration in the GBSS gene that completely eliminates GBSS activity. In rice a single nucleotide polymorphism at the leader intron 5′ splice site of GBSS gene has been shown to be associated with changes in amylose content due to altered efficiency of GBSS mRNA processing. A sequence of AGGTATA at this site is found to be associated with cultivars having an amylose content of above 18% as against a sequence of AGTTATA that is present in cultivars having lower amylose content.

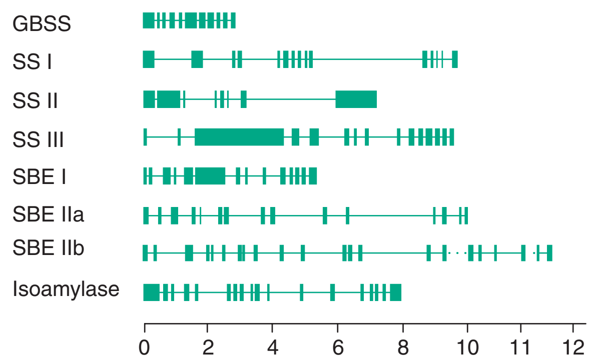

Figure 3 Structure of wheat starch biosynthetic genes. (Data from authors' laboratory.) Exon sequences are illustrated by the thick lines, intron sequences by the narrow line.

The locations of most of the starch biosynthetic enzyme genes are known in wheat and shown in Figure 4. Many of these genes are on chromosome 7.

Future Work

Genomics has essentially provided the whole genome sequence of Arabidopsis and rice. As rice is also an attractive model system for investigating reserve starch synthesis, it should be possible to identify all putative starch biosynthetic enzyme genes in the genome.

The function of such putative candidate genes can be analyzed by performing conditional knockouts of selected genes, and powerful RNAi technology is available for such experiments. Conversely, gene inactivation through tagging will also yield information about the role of candidate genes. This can arise either through the identification of the tagged gene and analysis of phenotype or by observing a phenotype and then identifying the gene inactivated. Both approaches will be highly informative.

Analysis of expression of all of the genes in a tissue by means of microarrays can also be performed. The ability to study the pattern of transcription of the whole genome by means of "chips" will facilitate the study of linked genes and pathways. If tagged mutants are compared with wild-type, then the total changes in transcription can be identified and pathways can begin to be deciphered. For untagged mutants or natural phenotypes, all the genes affected in a particular phenotype can be identified from microarray analysis of the expressed genes in bulked segregants differing in the phenotype studied.

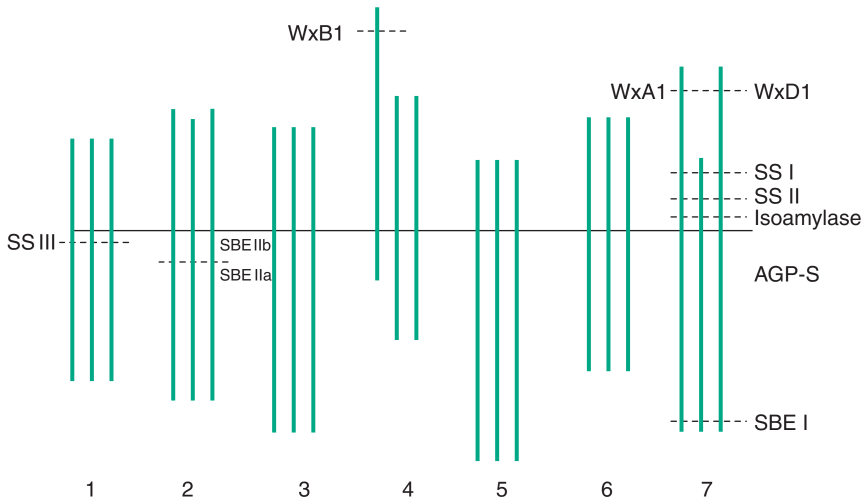

Figure 4 Chromosomal location of wheat starch biosynthetic genes. (Data from authors' laboratory observations and from the suggested readings.)

New Starches in Cereals

It is clear that with increasing knowledge of the enzymes involved in starch biosynthesis, the ability to alter the starch produced is also gained. New products and processes will need to be developed to capture any advantages occasioned by these new starches. Although such new phenotypes can be produced most easily by using transgenic technology, current public opinion would make it prudent to also produce starches by conventional breeding. The development of molecular markers and rapid breeding technologies (such as the production of doubled haploids, embryo culture and the ability to quickly extract DNA from small samples) will undoubtedly also speed up the production of novel types of starch by conventional breeding strategies.

Conclusion

The involvement of four classes of enzymes – ADPG pyrophosphorylase, starch synthases, starch branching enzymes, and de-branching enzymes – in starch biosynthesis is clearly established, although the precise roles of isoforms in many cases are not clear. Other enzymes may also have roles in starch biosynthesis. Starch phosphorylase and disproportionating enzyme (D-enzyme) are examples. The role in starch degradation of both of these enzymes is well known. However, their involvement in starch synthesis, although suggested from a few studies, is a matter requiring further research. The priming of polysaccharide synthesis and granule formation during starch biosynthesis is still unresolved.

Although it is evident that mutations in the core genes lead to specific starch phenotypes over a variety of species, species-specific characteristics are observed that are often significant and of practical importance. Understanding the complex nature of starch biosynthesis has always been facilitated and accelerated through investigations on model systems such as Chlamydomonas and Arabidopsis and increasingly rice. However, attempts should also be focused on individual species to be able to precisely manipulate the starch structure and functionality to suit specific end uses.

STORED GRAIN

Contents

Handling from Farm to Storage Terminal

D Richard-Molard, INRA, Nantes, France
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

Traditionally, grain production has occurred close to the site of its utilization, so the logistics of grain transport and storage have been relatively simple. However, with the advent of large-scale production in major grain-producing regions of the world, it is a very large undertaking to move the grain from the site of production via stages of transitional storage to the final destinations. This complex process may involve the movement of the grain from one side of the world to the other. Conservation of grain quality throughout its transport and storage is of critical importance. The technologies for doing so have developed enormously from the traditional times of subsistence farming.

Historical accounts from sixteenth-century Europe explain the importance, even then, of grain drying and

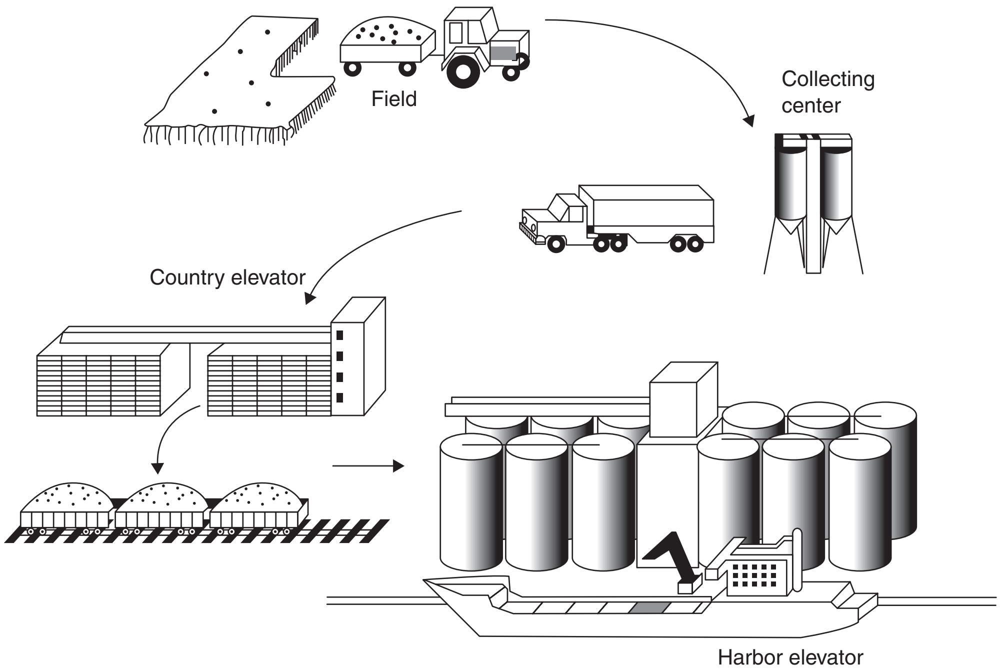

Figure 1 Grain collection, from field to terminal elevator, a long trip for the grain. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 1019, Elsevier Ltd.)

ventilation, and the use of modified atmospheres for the good conservation of grains. However, these texts did not explain the scientific bases for these practices. Today, with the development of scientific knowledge on the grain ecosystem and progress in the fields of building materials, sensors, and measurement techniques, grain storage technologies have been mastered.

New innovative technologies continue to be applied to the increasing demands of world trade in grains, particularly to the requirements for technological and sanitary quality. These are summarized in this article, with the degree of sophistication ranging from simple on-farm storage of seed for next season to an enormous terminal elevator, capable of handing and storing vast quantities of grain under hygienic conditions (Figure 1).

Types of Storage Needed at All Stages of Handling

The farm is the first stage of handling and storage. At its simplest level, on-farm storage may involve a pile of unprotected grain on the floor of a farm building. At the farm level, grain may be stored temporarily in small concrete or round steel bins of small capacity (25–100 t), which receive the crop immediately after harvest and before transport to a better long-term storage facility or in order to wait for the best market situation.

Grains may also be taken from the farm directly to a collecting center, a small storage installation with several small bins providing an average capacity of ~1000 t. This does not generally have machinery for grain cleaning or drying, since the grain is usually transferred soon after to an elevator (Figure 1).

Country elevators (5000–50 000 t), so-called because they are filled with grain elevated into them by rolling belts with buckets, receive grain from the individual producer or from small collecting centers. Their capacity is adapted to the seasonal production of the area, and their main role is to keep crops in good condition before and during storage, and to reload it into trucks or rail cars for transportation to terminal silos, export elevators, or industrial users.

There is no general rule for determining the best dimensions of a farm bin or a country elevator. Usually, the cost of storage increases sharply as the size of the silo decreases, so there is a tendency to build large structures. However, the grains are managed in multiple silos, where grains of different grades or water contents can be separated easily.

The terminal elevators are generally located close to trade centers and/or transportation terminals, such as harbors (Figure 2). Terminal elevators commonly offer storage capacities of 5000–500 000 t in the USA or northern Europe.

Equipment for grain handling and control is often basic at the farm level, with only very simple devices for grain elevation and ventilation. By contrast,

Figure 2 Harbor elevator in Rouen, France, with a total storage capacity of 300 000 t. This is able to load grains into vessels at a rate of 5000 t h^{-1}. (Photo courtesy of J Pfeiffer.)

country and terminal elevators have handling capacities adapted to their transportation facilities and usually have sufficient capacity for peak load handling during the short period just following harvest. Today, most are fully equipped with remote control and automation, so that grain can be automatically transferred from one silo to another or to ships and railway cars. Weighing, cleaning, sampling, and even several grain sample tests are now electronically controlled.

When possible, gravity discharge from grain bins is ideal, but the cost of the corresponding structures and equipment is high. Consequently, flat storage of cereals is also commonly carried out in many situations, both at the farm level and in terminal elevators, to provide additional storage capacities when necessary. Such flat-bottomed silos are emptied through a central outlet, where a rotating screw-conveyor draws the grain away beneath the floor. Many other sophisticated devices have been developed for moving the grain using air blown through metallic networks of ducts below the bins, or with suction blowers as back-up devices.

Maintaining Grain Quality during Storage

The freshly harvested grains must be tested on receival to determine the appropriate treatment for safe storage, such as cleaning, dust removal to avoid very dangerous dust explosions, drying, cooling, chemical treatments against insects, etc.

Grain moisture is the major attribute to be controlled during storage. Even with mature dry grain harvested at $\sim$12–13% moisture content, serious problems will be encountered within a few months if moisture cannot be properly managed to prevent the heat and moisture transfer that can occur in bulk during storage and transportation. It is, therefore, important to store grains with a sufficiently low initial moisture content to prevent mold development and biochemical changes, and to maintain this low temperature as constant as possible everywhere in the silo throughout the storage period. This can be achieved by artificially drying grains with excessive humidity at harvest, like maize in Europe, and by periodic forced ventilation during storage to remove excess water where condensation has occurred.

Monitoring Moisture during Storage

It is difficult to confidently determine the correct moisture level for a specific grain type in a given situation. Very general and theoretical rules can be given, but one should bear in mind that a large mass of cereal grain is never homogeneous in temperature, moisture, apparent density, thermal conductivity, etc., and so continuous monitoring with modern techniques, such as silothermometry, and periodical sample examination is highly recommended in every situation.

The thermodynamic activity of water, which represents the availability of water in the grain, is the most important physical parameter governing grain stability during storage, determining both biochemical changes and microbial growth. The availability can be estimated (and measured) by the equilibrium relative humidity (ERH) of the intergranular air in equilibrium with the grain. A nonlinear relation relates ERH to moisture content, as shown in Figure 3 for wheat and maize. This curve is named a "sorption

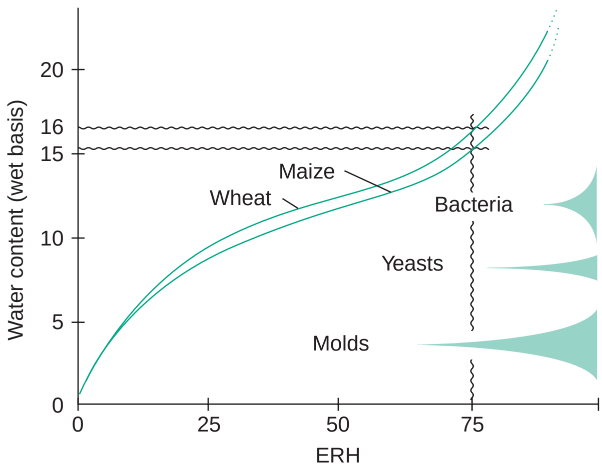

Figure 3 Sorption isotherms for wheat and maize at 20°C and zones of activity for the main causes of grain degradation during storage (the wider the zone representing a cause of spoilage, the more intense and rapid the spoilage). (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 1020, Elsevier Ltd.)

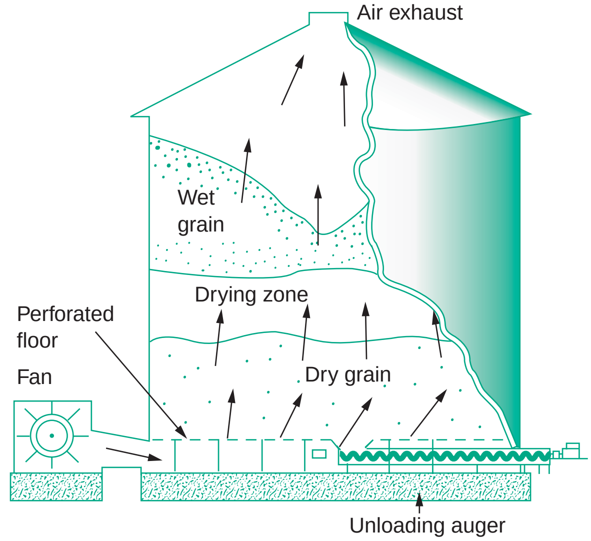

Figure 4 Farm bin for low-temperature drying. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 1021, Elsevier Ltd.)

isotherm" and depends on both the average temperature and the biochemical composition of the grain. It differs from one cereal to another, but its relationship to the level of deterioration by different causes, such as microorganisms or enzymes, remains constant to a first approximation. Wheat stored at 16% moisture content is in equilibrium with an ERH of ~80% and will undergo the same kind of degradation at the same rate as maize with 15% moisture content, which also has an ERH of 80% at the same temperature. As the temperature increases, the sorption isotherm is shifted to the left, i.e., at the same water content, there is a higher ERH, and spoilage is faster.

Silothermometry is a sophisticated technique, utilizing thermocouples placed in the silo able to detect slight variations in grain temperature, which indicate the beginning of deterioration through an aerobic process, resulting from a localized increase in humidity. Modern sensors can detect temperature changes of less than 0.5°C. In most situations, this gives sufficient sensitivity and overcomes the problem of the very low thermal conductivity of cereal grains, which allows temperature differences to be transmitted only over short distances in the bulk. With this method it is also possible to determine the best moment for drying and ensure the completion of grain cooling by nocturnal ventilation.

Drying Methods and Alternatives

The use of adequately dried grains for storage in silos is a mandatory condition (Figure 3). Many types of driers, such as full-bin driers, layer driers, continuous-flow driers, etc., are presently used on farms or in country elevators, but all utilize the same basic principle: heated dry air is blown through the grain to remove excess water. Figure 4 represents a farm bin equipped with a low-heat drier capable of drying grains with moisture contents of less than 20% (wet basis).

When large quantities of moist grain are to be dried rapidly, high-temperature drying is necessary. This gives a higher extractive capacity but can also cause thermal degradation of the grain, if used improperly, as often happens with maize, which is sometimes harvested with a water content as high as 35% (wet basis) in Europe. If the air for drying is too hot, the functional proteins are denatured, and the value of the crop is decreased. However, high drying temperatures destroy all forms of insects in the bulk.

When possible, a combination of different drying and cooling practices often gives the best technical and economic results. The essential principle is to decrease the moisture content rapidly to a level, thus decreasing the rate of mold development, i.e., to ~18% moisture in a first step, then to decrease the residual humidity to 15–16% by forced aeration when the ambient air is cool and dry enough to be efficient.

Natural Drying Methods

Alternative natural methods for grain drying have often been used, and at least two must be mentioned. The first, used mostly for maize, uses gentle drying by the wind of cobs stored outside in cribs or other forms of mesh silos. This is satisfactory, provided that the temperature remains sufficiently low to inhibit the growth of such toxinogenic fungi as *Fusarium* species.

The second type of natural drying method uses solar driers. These have been tested in efforts to save energy, but their use can be recommended only in regions where sufficient energy is provided by the sun to achieve drying in a time short enough to avoid spoilage by microorganisms. Unless drying to 80–82% ERH can be achieved in less than 7–10 days, the grain will certainly be damaged.

Modified-Atmosphere Storage

When cereals are not intended for uses requiring particular properties, such as a high germination ability for malt production or functional properties of proteins for breadmaking, it is possible to store them with a higher water content than usual, provided the oxygen is removed from the system.

Underground storage and storage in anoxic atmospheres in hermetically sealed silos, or silos continuously flushed with nitrogen, for example, are quite possible. It was recently shown that the nutritional value of wheat for animal feeding could be successfully maintained over several months by storing it, after grinding, in airtight conditions at 21% water content and 15–20°C. Storage of wet (35% water content or more) maize for pig feed in hermetic silos is now popular in several countries. Because of the important demand for intergranular oxygen at such a high humidity, especially through respiration of yeasts and lactic acid bacteria, the concentration of available oxygen remains extremely low in the silo. The growth of molds is inhibited and, at least until the silos are nearly empty, that is to say when free oxygen again appears and concentrations of carbon dioxide are decreasing, no mycotoxins can be produced. With such hermetic silos, it is not necessary to grind the humid grain in order to produce silage, and the commodity can be handled more easily than with traditional practices.

Control of Insects

Storage of dry or wet grains under modified atmospheres is an excellent way to kill insects, and modern techniques for storage of dry wheat under high concentrations of carbon dioxide have yielded very good results in Australia in recent years. Most often, if all living insects are to be killed, chemicals need to be used when infestations are detected in a silo or a ship.

Insecticides can be divided into two main classes: contact insecticides, which kill insects and prevent reinfestation owing to their remanent effect, and fumigants, which destroy insects without leaving any significant residues. Organochlorine insecticides, which belong to the first class, were extensively used in the past but are now forbidden because the toxicity of their residues is very high for humans.

Pyrethroids like deltamethrin, permethrin bifenthrin, and organophospates like malathion, dichlorvos or methyl pirimifos, are also contact insecticides, used at concentrations of ~4–8 g of active substance per tonne of grain. They are very fast-acting and highly toxic by contact and ingestion, but their residues necessitate careful consideration of the number and timing of treatments. Their relative inefficiency against the hidden forms of insect (eggs, larvae) that live within the kernels should also be mentioned.

The only current fumigant is hydrogen phosphide, which is used to rapidly kill all live insect stages, including adults. It is used in airtight structures equipped with systems that allow the gas to be introduced and removed safely.

Apart from modified-atmosphere storage under nitrogen or carbon dioxide, only persistent insecticides can provide good long-term protection for grain. It is then of primary importance to ensure that there is no residue in by-products like flour and brans used for human and animal food. At the present time, there is a general tendency to decrease the concentrations of toxic substances used against insect infestations. A possible approach would be to combine the use of carbon dioxide with an active substance, such as methyl bromide or hydrogen phosphide, which would permit a considerable reduction in the dose of fumigant used because of synergism with carbon dioxide, which increases the penetration of the active substance in the respiring stages.

The Future

All over the world, safe storage of cereal grains is a vital but expensive activity. Too many cereal grains are still used in the food industry despite the poor quality resulting from inappropriate storage conditions. Current scientific and technical knowledge in this domain is sufficient to answer the main questions about handling and storage of grain, but new trends are appearing: consumer demand for safe products, i.e., free of chemical residues, is growing fast. This probably means that the use of contact insecticides and even fumigants should be replaced by more acceptable techniques like physical techniques in the coming years.

Another trend seems to be a clear demand for identified grains, nongenetically modified grains, and grains from a precise geographic origin or a well-specified technological quality, for example. Such an evolution would certainly introduce very important changes in the way in which the grains are harvested, collected, stored, and distributed. Loading speeds as

high as 5000 t h^{-1} are often reached today in harbor elevators, but this is not the most convenient technology if small bulks of 50–100 t of well-certified grains are to be prepared.

Invertebrate Pests

P C Annis, CSIRO Entomology, Canberra, ACT, Australia

Introduction

A storage filled with grain represents a large and delimited resource of biologically available energy. Under many conditions this resource will become the home for a range of invertebrate pests unless some positive action is taken.

Much of the basic information on these pests was obtained prior to the early 1980s and is consequently not accessible electronically. Two series of international conferences – "The International Working Conference on Stored Products Protection" and "The Conference on Controlled Atmosphere and Fumigation in Stored Products" – are useful to keep track of modern thought on the entomological aspects of stored product science.

There remain many gaps in the scientific study of invertebrate grain-storage pests. Furthermore, the type of studies needed to fill in these gaps are usually time consuming and require a considerable number of person hours to complete. This means that they are unlikely to take place in contemporary circumstances where both time and money are scarce resources. This article aims to give a broad overview of what is known and what can be implied from this knowledge and to direct the reader to some of the less-referenced but important sources of information.

The Stored Grain Ecosystem

The stored grain ecosystem is characterized by copious food, limited water, and a stable thermal and humidity environment. It can often remain predator free and can remain undisturbed for significant periods of time. These conditions can be ideal for the development of large infestations of a number of specialist invertebrate pests. The vast majority of these pests are either insects, Coleoptera (beetles), Lepidoptera (moths), and Psocoptera (booklice), or Acarina (mites).

Grain Invertebrates

Detection and identification of stored-product pests is not always easy. Many of the insects that infest stored products are small, less than 5 mm in length and only 1 mm wide. Some are much smaller, particularly psocoptera and mites, which may be less than 2 mm long and easily mistaken for dust, were it not for the fact that they move.

The patterns of development of stored-product pests also complicate detection. Some species go through their early developmental stages inside the grain kernel with little or no external evidence of their existence. Others complete their life cycles between or on the surface layers of the grain. Others periodically move in and out of the grain and its storage structures. More details on the identification and biology of individual species can be found in the specialist literature referenced at the end of this article.

The most widely used method of detection of insects within a bulk of grain is sampling and sieving. Samples are taken at random (but sometimes targeted) and then sieved through an appropriate mesh, which allows the pest and dust to pass through, while the grain is retained. Samples are taken either from moving grain or probed from static grain. This is an ideal method for sampling free-living adults but of no use for immature stages developing in the grain,

or eggs attached to the grain. Sieving can be automated and this is often done at large grain terminals. Assessment, counting, and identification however remain a manual operation. Probing and sieving of grain bulks is a very labor-intensive operation, especially if a high level of detection is required.

Trapping is also used as a means of detection, and it can detect very low infestation levels for some species. The traps can vary from a simple pitfall trap, through refuge traps to pheromone-baited traps. The major problem of trapping is to understand the significance of the numbers trapped in terms of the numbers actually present in the grain and surrounding areas. Not all species are equally trapped so the significance of low numbers in a trap may range from very low for an easily trapped species, to very high for a hard-to-trap species.

Why Are Some Invertebrate Pests Important?

The magnitude of almost all the problems created by invertebrate pests in grain is more or less proportional to the number of insects present. The only notable exceptions to this are when detection of a single insect of quarantine interest may have the same impact as detecting many hundreds. A similar circumstance applies to exporters who ship grain to a standard that specifies no live insects.

The number of invertebrates present in any parcel of stored grain depends first on the number in the initial population. This population may come in with the grain, it may have been a resident population in the empty storage, or it may have entered the storage after the grain had been in storage for some time.

The next determinant of population size is the rate of increase in the population. This is determined by the often-complex demographic attributes of the species. Rate of increase can be approximated to the time it takes to develop from egg to reproductive adult and the number of surviving progeny from one set of parents. Both of these demographic parameters are strongly influenced by the grain type, density of insects, moisture, and temperature, and can vary widely between species. Even more simply it can be expressed as the multiplication factor per unit time (Table 1).

The Consequences of Invertebrate Infestation

Biomass Consumption

This is the first and most obvious consequence of invertebrate infestation. An uncontrolled coleopteran infestation in favorable environmental conditions can change a pile of grain to a pile of dust in about four generations (where development time takes 25–50 days from egg to adult). This is a worst-case scenario and assumes no action is taken to reduce or remove the infestation. In reality, the biomass-loss rates due to invertebrates are usually much less even in primitive storage conditions. However, figures up to 40% are sometimes reported and losses of 10–20% are common. In well-managed grain-handling systems, the losses are so small that they are hardly assessable (e.g., much less than 0.1% in the Australian bulk-handling system). This range in the amounts of biomass consumption is almost entirely due to the numbers of insects and their multiplication with generations (modified by species, temperature, and relative humidity of the intergranular air or the associated grain-moisture content).

There is a reasonable body of literature on the energetics of a range of stored products coleoptera. A single beetle requires in the range of 40–250 J (depending on species, temperature, and relative humidity) to develop from egg to mature adult while a single grain of wheat (~0.035 g) is able to provide 530 J on average. Using simple arithmetic, it is easy to estimate loss rates under a worst-case scenario when each female beetle produces 100–300 viable progeny in a lifetime under optimal conditions. In the case of stored product, Lepidoptera *Ephestia cautella* and

Table 1 Rate of population increase, development time, and longevity of a range of common pests of stored grain

Common name of group (scientific name of group)	*Species*	*Multiplier of increase in 4 weeks*	*Development time (days)*	*Average adult longevity (weeks)*
Beetles (Coleoptera)	*Sitophilus oryzae*	24	25	5
	Rhyzopertha dominica	29	25	4
	Tribolium confusum	60	20	11
	Cryptolestes ferrugineus	60	21	7
Booklice (Psocoptera)	*Liposcelis bostrychophilus*	22	21	2
Moth (Lepidoptera)	*Ephestia cautella*	50	25	1

All data are given at optimal conditions of temperature, moisture, and culture medium.

Plodia interpunctella consume higher amounts of energy, ~600 J per individual (34 mg), during their lifetime.

There is little energetics or demographic data for the Psocoptera of stored grain, but it is likely that their rate of respiration on a body-weight basis is at the high end of the beetle range. Their mass is ~1% of that of a typical stored grain beetles which would imply a lifetime energy requirement of ~2 J per insect or 0.1 mg biomass consumption per insect.

There have been two energy studies on mites infesting stored grains. *Tyrophagus putrescentiae* and *Acarus siro* have a lifetime energy consumption of 2.5 and 2.8 J, respectively. This translates to a biomass consumption of ~0.1mg per individual. Mites in general are capable of explosive population growth in favorable conditions with an increase of 2500 times in one month, as quoted in several references.

Grain pests are sometimes classified as primary and secondary pests. In general, primary pests are ones that can be found on their own. Secondary pests tend to appear after the primary pest. It is often claimed that only "primary" grain pests are important in grain consumption, but the energy requirements of "secondary" pests are little different to those of primary pests, and in a large infestation the only source for most of that energy will be the stored grain.

Quality Damage

In addition to biomass loss, invertebrate pests feeding on grain may cause a wide range of quality damage. This damage may be generalized or specific depending on the size of the infestation, the species involved, and the grain being attacked. General damage results from insect-induced heating, unselective consumption of biomass, and webbing of grains. Specific damage occurs when the pest consumes critical components of the grain.

Reduction in germination of seeds is a common consequence of germ-consuming insects or infestations that cause significant heating. Insects consuming the endosperm will cause considerable reduction in seedling vigor together with some reduction of germination. It follows that there is a commensurate loss of nutrients associated with consumption of specific parts of the grain rich in those nutrients.

Generally, the results of infestation at a chemical level have been likened to an apparent acceleration of those types of effects seen in the natural aging of grain. This may be due to any or all of the following: heating, consumption of specific energy-rich components, removal of protection against oxidative changes, odor, and discoloration.

Contamination

The presence of a few insects, alive or dead, is rarely a direct problem to users or consumers of grain. Large infestations may create problems with feed rejection where grain is used as stock feed. Large infestations of *Tribolium* species and of the mite *Acarus siro* may give rise to objectionable odors related to specific metabolic by-products of these species.

Downstream food-processing industries are often required to produce a product containing less than a defined number of insect fragments per gram. Meeting this requirement is greatly assisted by low numbers of insects and insect fragments in the raw materials.

The real influence of contamination of grain by insects and insect fragments is through their role as quality criteria in the trading of grain. For example, grain cannot be exported from Australia if it contains detectable live insects. In other parts of the world, different standards may apply but there is usually an insect-related quality criterion associated with traded grain.

Indicators of Poor Storage

The presence of insects in grain is a useful indicator of how well the grain has been managed during storage and the extent to which deterioration has occurred. Large infestations rarely occur in well-managed storages and are often associated with poor storage hygiene, the presence of birds and rodents in and around the grain, and with hotter and wetter grain than is optimal for storage.

Allergy

Allergic reaction to living insects and mites is a common phenomenon, although only a few stored grain insects feature as commonly reported causes of allergic reactions, while an allergic response to insect fragments has occasionally occurred in humans consuming or handling infested grain. Amongst the coleopterans *Sitophilus granarius* and *Rhyzopertha dominica* have been known to induce asthma and similar respiratory problems, psocids of the *Liposcelis* group have caused similar problems, and the hairs of dermestids cause skin irritation. Handling Lepidoptera, in general, has been known to cause dermatitis and allergies. Skin irritation and allergy to a wide range of mite species is very well known.

Collateral Problems of Control

An important consequence of infestation is the need to control the infestation. This is frequently achieved by fumigation (the use of a toxic gas) or by

using a contact insecticide (a grain protectant). The essential difference between these two is that the active phase of fumigants is a gas or vapor while that of grain protectants is a solid or liquid. The major operational difference between the two types of chemical is when and how they are used.

Fumigants can be applied at anytime during storage as long as the gas concentration can be retained or made up. Fumigants can be purged from the storage rapidly and the grain can become available for use in days. Fumigants tend to leave low levels of residues and alteration products. They do not offer any protection to the grain from invading insects once the gas is removed.

Grain protectants can only be applied to moving grain and are most commonly applied as grain enters storage or is moved between storages. Chemicals are effective as protectants because they stay in an active form for significant periods, and therefore residues are an important consideration.

Besides national regulation concerning what chemicals (and what rates of application) may be used on grain, there are international agreements set down by the Codex Alimentarius Commission. Despite the national and international regulations and agreements individual customers may have their own standards for treatments and residues depending on the end use of particular parcels of grain. The organic grain market requires grain that has not been treated with any fumigants and grain-protectant chemicals.

Insects and Mites as Vectors

There are many reports of invertebrate pests and mites in particular, acting as vectors for fungal spores. If the environmental conditions are then conducive (water activity greater than 0.7), active fungal infection can result. Some stored-product pests can be vectors for parasites and food-poisoning organisms, but only under conditions of poor hygiene.

Insect and Mite Control

Effective and economic control of insect and mite infestation requires a combination of several different types of action all aimed at ensuring that the grain remains effectively free of insects during the storage period. These types of actions are: hygiene, inspection, disinfestation, and protection.

Hygiene

Hygiene is fundamental to good pest control, and a properly implemented hygiene operation goes a long way towards complete pest control. The aim of hygiene is to ensure that the starting population for a potential infestation is small and that the risk of infestation from outside the stored material is very much reduced. Hygiene starts with structure and plant design and, to a large extent, good hygiene can only be as good as the construction of the storage and handling structure will allow. Details of designing for hygiene are well beyond the scope of this article and are poorly documented in the literature. However, the general principles are simple. They include making sure that there are no places where grain (or grain dust) can accumulate and remain undetected and undisturbed for long periods. For insect and mite control, dust, spills, and accumulations which can be seen and easily removed are not a problem. It is residues that remain hidden from easy inspection and removal that are the cause of many infestations. A second feature of a well-designed storage is a physical barrier to infestation from outside the storage. Such a barrier should also restrict the access of birds and rodents whose presence is a problem but may also help establish sites of infestation in nest materials. A barrier that provides complete sealing will also improve the efficacy of fumigation.

Where a storage has not been designed with some consideration to hygiene, it may be possible to modify problem-causing features. This is not without its own problems since it can produce even more inaccessible spaces that entrap residual grain and dust.

Work Procedures and Skill

The day-to-day practice of hygiene is a routine and dull job that can be labor intensive. It is, therefore, essential that hygiene tasks are carried out thoroughly; otherwise the resources invested are wasted. A hygiene checklist is an essential tool for good hygiene management. This list ensures that all the important places are drawn to the operators' attention.

Once a storage and its surrounds have been cleared of all detectable grain and grain residues, there may be some advantage to treating these areas with a surface structural treatment of a contact insecticide or an inert dust.

Inspection

There are three generic times when inspections are carried out: on intake; during storage; and at outturn. Outturn is often the most important as far as the next user of the grain is concerned, but in pest control terms the least useful. Disinfestation of grain at outturn is impossible and the options for the rapid disinfestation (<24 h) of detained grain almost nonexistent (see methyl bromide fumigation).

In a well-managed grain handling and storage facility, the infestation status of grain at intake largely

determines the starting population of insects. In cases where grain with infestation is taken into storage, it is important that it is disinfested before mixing with uninfested grain. A thorough cleanup of the grain path should be carried out before the path is used for uninfested grain.

Inspection during storage is strategically the most important inspection. There should be an insect-free period of about three generations, i.e., ~3 months at or above 25°C for the majority of species. In situations where hygiene has been adequately carried out, intake inspection was effective, and any infested grain disinfested. After three months any minute residual initial infestation (or invasion) is likely to have reached detectable levels. After three months postintake, or following disinfestation, a monthly inspection is recommended.

Chemical Control

Fumigation

Fumigation for control of infestation can be employed in two ways: prophylactic, where a treatment is carried out routinely, usually shortly after intake, even if no insects or mites are found on inspection; or tactically when it is carried out at the first signs of infestation. Good fumigation used with good hygiene and adequate sealing should not need repeating as the recommended application procedures are designed to give a total kill of all insects. Where a reinfestation appears after fumigation, it is most probable that either the fumigation was not carried out adequately or reinfestation pressures are high. Fumigation only works properly if adequate concentration can be maintained for an adequate exposure period. These conditions can only be achieved in a well-sealed system for a single application of fumigant or by "continuous fumigant addition" in an adequately sealed system.

Currently, phosphine and methyl bromide are the only grain fumigants in widespread use for fumigation of grain.

Phosphine

Phosphine is applied in two physical forms, as a metallic phosphide (usually aluminum phosphide) or as gaseous phosphine from cylinders. Phosphine requires a significant time to be efficacious and is not able to kill all pest species at every stage below a nominal threshold concentration, no matter what the exposure period (within commercial reality). These approximate conditions are shown in Table 2 for both phosphine-resistant and nonresistant pests.

The main issues around the continued use of phosphine are the worldwide occurrence of resistant populations and concerns about its safe use.

Metal Phosphide

The most common type of phosphine treatment is where a metal phosphine-based formulation is applied to the grain in a variety of physical forms: pellets, tablets, plates, bags, blankets, and chains. All these forms are designed to allow a controlled release of phosphine as the phosphide reacts with water contained in the air surrounding the commodity or on the surface of the commodity. The rate of release depends on a number of factors: the metallic component of the phosphide (magnesium is faster than aluminum); the surface area to volume ratio of the physical form; the degree of compression (powders are faster than compressed formulations); and other components mixed with the phosphide, temperature, and water vapor availability.

The rate of release and the level of sealing of the fumigation enclosure are the principal determinants of the concentration profile over a period of time. The magnitude of the concentrations (but not the shape of the profile) is modified by the presence of commodity and the amount of phosphide added.

Gaseous Phosphine

A more recent application technique for phosphine involves the use of gaseous phosphine. This requires careful control as phosphine can be explosive in air (1.8%, 18 000 ppm) and the gas is usually supplied as phosphine mixed with a nonreactive gas, such as carbon dioxide or nitrogen, to assist in eliminating the explosion risks. The gas is then further diluted with air to give the required concentration. This is done on a continuous basis for flow-through fumigation or as a single application for a sealed fumigation.

Table 2 Exposure period in days required at various threshold concentrations to ensure disinfestation with phosphine

Concentration	*PPM ($g\,m^{-3}$)*	*10 000 (14)*	*2500 (3.5)*	*250 (0.35)*	*100 (0.14)*	*25 (0.035)*	*20 (0.027)*
Exposure time (days)	Susceptible	1.5	2	8	10	25	30
	Resistant	1.5	2	10	>30	>30	>30

Methyl Bromide

Methyl bromide has been the mainstay of rapid disinfestation for many years. Unfortunately it has been shown to be a potent stratospheric ozone depleting substance. This means that its use has been severely curtailed, and under international treaty it will only be available for genuine quarantine and related preshipment uses.

Fumigants under Development

Attempts are being made to find replacements for methyl bromide and alternatives to phosphine. Carbonyl sulfide, ethyl formate, and sulfuryl fluoride all show some promise at the research level but are not yet available for commercial use on grain. Even if they are found to be satisfactory, there are commercial and regulatory issues still to be resolved. There is a chance of registration of all these products in Australia in the next 2–3 years.

Controlled Atmospheres

Controlled atmospheres can be thought of as a special case of fumigation, where the gases used are normal components of the atmosphere and biological systems. The gases most commonly used are nitrogen to displace oxygen, and carbon dioxide. There are only a few places around the world where controlled atmospheres are used routinely. The main problems with controlled atmospheres are long exposure times (typically 15 days or longer), the need for a high level of sealing, and the large volumes of gas required to establish or maintain concentration of $>40\%$ for carbon dioxide and 99% for nitrogen ($<1\%$ oxygen). Despite these limitations both types of controlled atmospheres are used where these constraints are not limiting, or where special requirements exist.

For example, nitrogen is used in Australia at the GrainCorp shipping terminal at Newcastle, New South Wales where a large grain-storage capacity allows grain to be held for treatment. There is a large industrial source of liquid nitrogen close by, and the storage has been constructed to a suitable level of gastightness. Carbon dioxide is used to disinfest organic grains exported in shipping containers from Australia to many parts of the world.

Grain Protectant Chemicals

Grain protectants (i.e., insecticides approved for direct application on grain) can be a very effective way of controlling invertebrate infestation. In the past they have been widely used and have resulted in spectacular reductions in insect infestation. For example, the introduction of malathion treatment in the 1960s resulted in a fall in the level of infestation in Australian wheat imported into UK from $\sim$90% of cargoes to well under 20% over a period of 5 years. The use of grain protectants has lost popularity over the last few years as a direct and indirect response to a perception of concerns about residues. This has led to it being strategically easier to store, handle, and market grain with "no residues" as it is more versatile at the moment of outturn (i.e., if it has no insects, it will suit most markets). Improved fumigation technology has helped this movement away from protectants in many places.

Physical Control

Invertebrate control by manipulation of the physical environment has been widely discussed. The use of heat, cold, aridity, shock, radiation, and separation appears in the literature. None are widely used in modern handling systems, due largely to their higher capital cost relative to chemical treatments such as protectants and fumigants. The only exception is the use of ambient air aeration, which is rarely used directly for insect control but slows the rate of population increase by reducing the grain temperature (although it is not necessarily effective for mites).

Future Prospects

Control of invertebrate pests in storage is likely to remain an important part of grain storage and handling for as long as the storage of grain remains a vital component of feeding the human population. Controlling these pests is likely to become more challenging as economic, environmental, and biological pressure increase.

Pressures to reduce the cost of storage and handling mean that labor-intensive activities such as routine hygiene, sampling, and pest detection are seen as costs that have to be reduced. Pressures for just-in-time delivery mean that reliable but slow-acting pesticidal activities are becoming more difficult to accommodate. International competition means that commodity prices are critical and any additional on-costs must be avoided where possible.

On the environmental side, there are continuing concerns of emissions of fumigants to the atmosphere, chemical residues on treated grain, worker safety, and the energy costs (dollars and greenhouse gas emissions) associated with pest control. All these reduce the number of readily available options.

The final pressures are the biological ones including the inevitable move of the pest gene pool towards

resistance to chemical and possibly physical treatments; the ability of invertebrate pests to capitalize on new niches created by new crops, new storage strategies, and any other opportunities created as systems change.

The prospects for registration of new commercially viable grain-protectant materials are not good. However, there is a possibility of some new fumigants becoming available over the next few years. Large-scale physical and biocontrol remain promising at the research level but have massive cost and logistical barriers to overcome before they can become commercial realities.

Pest Management

F Fleurat-Lessard, INRA, Villenave D'Ornon, France

Introduction

Insect infestation is one of the major causes of rejection of grain deliveries to grain stores, terminal elevators or processors, or at least a cause of downgrading of a grain delivery. Yet, there is little information available about the real rate of rejection or downgrading in domestic uses or at export. The level of 3–5% rejection is considered a realistic estimate for grain deliveries to processing industries in developed countries. The first threat with insect infestation in grain is related to the great power of multiplication of the majority of insect pest species that infest grain. In optimal conditions, the multiplication rate of the rice weevil, *S. oryzae*, is 25-fold in a month (Table 1). For the very common grain beetle *O. surinamensis*, this rate climbs to 50-fold. Insect detectable density in a grain bulk with an ISO standard method is rather high (not less than one insect per kg). Nevertheless, no detectable insect infestation is acceptable (and accepted) in the grain trade. This rule is applied worldwide, whatever the grain final destination and the level of infestation in domestic grain stocks. Consequently, the eradication of insect infestation of grain lots destined to a long period of storage is of prime importance for sanitary quality retention.

Insect Pest Control by Chemical Means

Chemical Insecticides

The most popular method to control grain infestation relates to the use of chemical pesticides. There are two main kinds of insecticides that can be applied on grain: contact chemical insecticides and fumigants. Each of them has a very different scope of use.

Grain can be protected by chemicals during binning or during handling, which are applied onto moving grain, conveyors, or at the elevator. Considering the low cost of such chemicals, a large proportion of cereal grain held in commercial stores is protected against insect infestation by chemical protectants. Grain protectants generally are insecticides registered

Table 1 Ecophysiological characteristics of the various insect and mites species living in stored grain – developmental temperature and rh threshold, natural rate of increase, and multiplication factor in optimal conditions

	Grains more often affected	*Conditions for development*		
		Temperature range (°C)	*rh range (%)*	*Population increase rate (28 d)*
Insect species				
Corcyra cephalonica	Rice	17–35	15–90	10
Cryptolestes ferrugineus	Wheat/barley	20–40	40–95	60
Cryptolestes pusillus	Cereals/pulses	18–38	45–100	10

Prostephanus truncatus	Corn/sorghum	18–37	40–90	25
Rhyzopertha dominica	Wheat/corn/sorghum	18–39	25–70	20
Sitophilus granarius	Wheat/rye/barley	13–33	55–100	15
Sitophilus oryzae	Wheat/barley/rice	17–34	45–100	25
Sitophilus zeamais	Corn/sorghum/wheat	17–34	45–100	25
Sitotroga cerealella	Corn/sorghum/rice	16–35	25–80	50
Stegobium paniceum	Cereal/by-products	15–35	30–100	7.5
Tenebroides mauritanicus	Corn/cereal products	18–37	25–100	2.5
Tribolium castaneum	All cereals/oilseeds	20–40	10–95	70
Tribolium confusum	Cereal products	20–38	10–100	60
Trogoderma granarium	Durum/oilseeds/pulses	24–31	1–73	12.5
Mites species				
Acarus siro	Wheat/oilseeds	7–30	65–95	2500
Tyrophagus putrescentiae	Oilseeds/cereals	12–35	65–95	20 000

for application on to whole grain to protect it against insect attack. There are basically two types of insecticides: (i) residual (i.e., long-term persistence substances that leave active residues on grain during several months to more than a year after the treatment) and (ii) nonresidual (rapid killing substances related to a high vapor pressure and a high liability of residues). The first group is mainly composed by organophosphates, pyrethroids, and insect growth regulators (IGRs) that are the active ingredients of the formulations. Only the dichlorvos (also an organophosphate) enters the second category.

Grain protectants are applied on grain mainly as a liquid formulation by simple spraying with air-powered applicators that can automatically be driven in well-equipped storage installations. However, powder formulations are still available and are useful for complementary treatments of the regions of a grain bulk that are favorable for insect development such as the surface layers in flat-bed storage that must be protected from external reinfestation after fumigation or cooling.

The use of grain protectants varies widely with the country, market preference, and local regulations (Table 2). Contact insecticide admixture in stored grain is widely used in grain-exporting countries and especially in France where four organophosphates and two pyrethroids are registered. In contrast, there is a marginal use of fumigation or controlled atmospheres (CAs) in France, unlike in Australia, North America, or in Germany. Because of heat degradation, insect resistance, increased buyer's concern, and more stringent requirements for registration of new molecules, the use of chemical protectants is declining in almost all the developed countries. Nevertheless, the maximum residues limit (MRL) for any active substance registered for direct application on grain forms the object of a worldwide approval by the *Codex Alimentarius* (joint commission WHO and FAO). The World Trade Organization had adopted these approved MRLs in cereal grain international trading.

The IGRs have been registered and used on a small scale in Australia. They are considered as substances with a poor efficacy during the weeks after the treatment and, even if they have a high lethal effect on insects, the populations are reduced to nothing only after weeks or even months after the application. These slow-active substances may be considered not to be useful by many grain handlers who expect a rapid effect in destroying existing infestations.

Today, more than 100 strains of stored grain insect species have been described resistant to organophosphates (chlorpyryfos-methyl, pyrimiphos-methyl, malathion, etc.) in different countries. The lesser grain borer, *Rhyzopertha dominica*, is certainly the most tolerant species to organophosphate treatment and, thus for this particular species, pyrethroids (deltamethrin, bifenthrin, or bioresmethrin) are preferred. This "adaptation" of insecticide treatment

Table 2 Chemicals (active substances) registered for direct application on cereal grain with their main characteristics and the MRL level fixed by the *Codex Alimentarius* Commission

Insecticide	*MRL Codex Alimentarius (mg kg^{-1} grain)*	*Oral LD_{50} for rats (mg kg^{-1} body weight)*	*ADI for human consumption (mg kg^{-1} body weight)*
Bioresmethrin	1	7070–8000	[a]
Bromophos	[b]	3750–8000	0.04
Carbaryl	[b]	850	0.01
Chlorpyrifos-methyl	10	1630–2140	0.01
Deltamethrin	1	135–5000	0.01
Dichlorvos	2	56–108	0.004

to the characteristics and the threat of a target insect species is one of the principles of Integrated Pest Management (IPM) strategies (*see* **Stored Grain**: Invertebrate Pests).

Fumigation with Gaseous Fumigants

Preliminary considerations Fumigants are volatile chemicals that are under a gaseous state at normal atmospheric pressure and ambient temperature, and which have toxic properties against insects. Once in gaseous form, the fumigants readily penetrate into infested kernels, thereby eliminating all insect life stages if applied properly. Numerous fumigants have been evaluated since the first discovery of the insecticidal properties of methyl bromide by Le Goupil in 1932. Although methyl bromide has played a major role in quarantine fumigation for international trading and for structural fumigation, there are few examples of its systematic use for grain fumigation. Recently, it was incorporated to the list of compounds possibly contributing to the depletion of the upper atmospheric ozone layer. Consequently, the use and production of methyl bromide will be forbidden in 2005 in all the developed countries. Two other fumigants that have been used for grain disinfestation were registered after methyl bromide: hydrogen cyanide (HCN) and phosphine (PH_3). The first one is only used rather exclusively for the treatment of empty holds of ships prior to loading. Only one fumigant is currently used worldwide for grain disinfestation: phosphine. Phosphine gas is generated from solid formulations of aluminum or magnesium phosphides. With its low molecular weight and low boiling point, phosphine is easily penetrating into grain bulks and inside grain kernels and diffuses through permeable packaging material. In addition, the adsorbed gas is quickly eliminated after fumigation by aeration. One disadvantage is the long exposure period needed to completely eliminate the target insect species population. The time to reach maximal concentration in the fumigation enclosure varies with the formulation, magnesium phosphide generators releasing phosphine more rapidly than aluminum phosphide. Nevertheless, complete efficacy of phosphine fumigation needs at least 3–7 days and even more with temperature levels between 10°C and 15°C. Below 10°C, phosphine fumigation is not recommended and can lead to efficacy failures very easily. Consequently, phosphine fumigations are performed during the warm season on grain at a temperature above 10°C.

Implementation of phosphine fumigation Phosphine gas is released from a solid generator through the action of the water vapor of air (occupying the intergranular space in a grain bulk). In these conditions of slow release of the gas during time, a specific unit of exposure was defined in 1984 by a Canadian researcher. He described the use of a "ct" term, in which the concentration of the fumigant and the time of exposure (usually in hours) are multiplied to quantify the "dose" for fumigation conditions. Other conditions of the fumigation influence the penetration and the efficacy of the fumigant for the killing of the target insects: temperature, relative humidity (rh), insect species, developmental stage, airtightness of the enclosure, or of the grain bin sealed for fumigation purpose. Modeling of the release of phosphine gas and the level of observed "ct" with fumigation conditions may allow the monitoring of the entire process and standardization of procedures in order to minimize the risk for workers.

An important aspect to consider with a gaseous treatment is the lack of residual protection, so reinfestation can occur immediately the grain has been aired and the gas concentration fallen below the safe concentration for workers. Fumigation with phosphine is used in two different manners: as a preventive or as a corrective treatment. In most cases, fumigation is applied when a grain bulk is obviously infested with insects and when the term of storage is not achieved. However, in the two countries, Australia and the USA, where it is the major method for insect control, it is preferably used as a preventive method for pest control. In these two countries, the policy of long-term storage of large quantities of grain in low-cost structures (flatbed storage, semi-underground pits or "grain bunkers," hemispheric storage bins, etc.) renders the use of fumigation indispensable. The difficulty to move grain to another bin equipped with different control means (cooling or liquid insecticide treatments) is also a major issue that can be solved by this technique. In this particular case, the storage structures dedicated to fumigation are built with permanent sealing during the whole period of storage in order to achieve several fumigations per year. In other cases, where fumigation is used for a complete disinfestation of infested grain, this operation can be carried out in specialized airtight bins called "hospital bins." The most popular technique which has the agreement of regulation authorities of many countries is called the "J system" (Figure 1).

Safety use considerations Very strict safety procedures are associated with the use of fumigants in developed countries such as specialized training, capability to monitor the concentration during the whole operation, and the use of safety equipment.

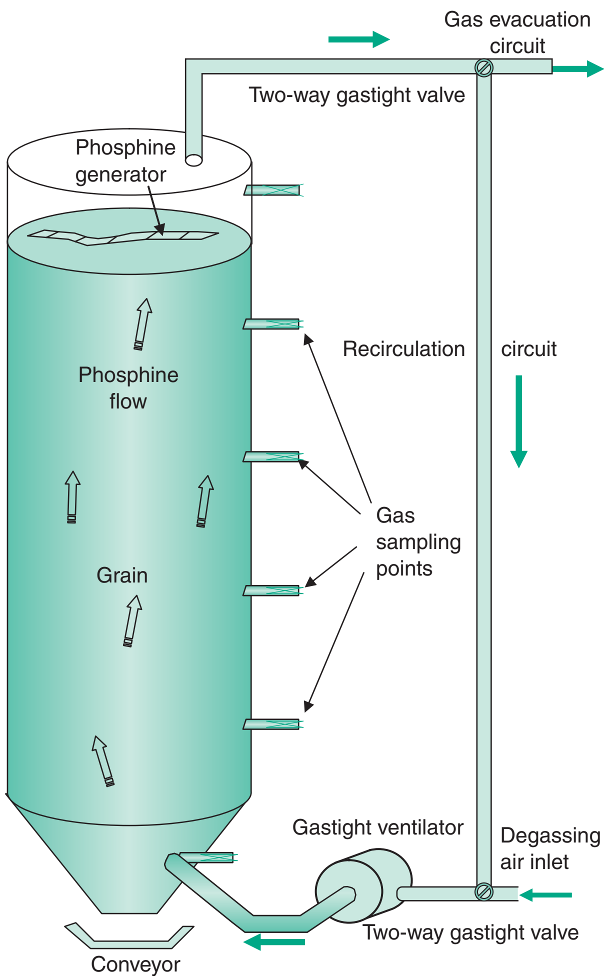

Figure 1 Design of an airtight grain bin devoted to phosphine fumigation operations ("hospital bin") – This bin is equipped with a gas re-circulating duct, an open aeration circuit and airtight ventilator and valves ("J system" principle).

So, this job is done by trained, reputable professionals. In developing countries, fumigation of durable food products is used as a complementary or marginal technique and most often regarded as a measure of last resort, also for safety reasons. Where regulations permit, in-transit fumigation of bulked and bagged grain on board ship can be carried out. This technology is widely used for grain export mainly in the USA. Other countries that require grain to be free of infestation at the point of export cannot use in-transit fumigation.

Phosphine – more recent issues In order to limit the main drawbacks of phosphine treatments – i.e., the (long) time needed for the natural release of hydrogen phosphide, and the difficulty to accurately deliver the expected dose from the solid generators – several methods have been developed to directly release phosphine gas. Generally, these gaseous formulations of phosphine compressed in gas cylinders contain 2% phosphine mixed to 98% carbon dioxide. Various systems have been patented and are currently used, especially in Australia (Siroflo®, Phosfume®, Profume®, etc.).

Probably because phosphine is of worldwide use today, several strains of grain insect species (e.g., *Rhyzopertha dominica* and psocids) have been shown resistant to phosphine fumigation in several countries. Consequently, there is recent enhancement in fumigation technology. In addition, active research has been launched for a decade in order to find new fumigants either for the replacement of methyl bromide or to overcome problems with target insect resistant strains. Today, there is very active research on sulfuryl fluoride and on carbonyl sulfide as the two major candidates for the registration of new fumigants that should replace methyl bromide.

Insect Pest Control by Physical Means

Temperature Control of Insects

Effect of temperature on insects Most of the insect species living in stored grain are of tropical and subtropical origin and have fairly high temperatures for optimal development (Table 1). Cooling grain below 20°C greatly reduces the rate of increase of the most noxious species called "the primary feeders": *Sitophilus* spp. (the weevil species complex), *Rhyzopertha dominica* and *Prostephanus truncatus* (the lesser and larger grain borers, respectively), and the juvenile instars of *Sitotroga cerealella* (the Angoumois grain moth). The population growth of all grain insect species is inhibited (natural rate of increase reduced to zero) when temperature falls down below 10°C (lower limit of developmental temperature for the more tolerant species of primary feeder to cold: *S. granarius*) (*see* **Stored Grain**: Invertebrate Pests). Accordingly, the lowering of grain temperature to this level of 10°C is the ultimate objective of grain cooling in order to control the insects. In most cases, grain temperature in a range 15–18°C will reduce insect damage to acceptable levels. Thus, the safe temperature level to reach is 15°C or less considering that in this condition the rate of increase of insect populations remains very low or is nil. But, the cooling process being slow due to insulating properties of grains, reducing grain temperature to this low level requires several aeration periods. These cooling steps are generally obtained by 1–2 weeks of aeration, mainly achieved during the night. The most important

cooling step is the immediate period after grain harvest. In addition, secondary insect species such as the saw-toothed grain beetle, *Oryzaephilus surinamensis*, the rust-red grain beetle, *Cryptolestes ferrugineus*, or the flour beetles of the *Tribolium* genus may move in great numbers during the aeration time to reach the opening at the surface where air flow goes out the grain bin. The more rapidly the first cooling step is achieved, the longer is the safe storage period. This first step has the objective to reduce the temperature to ~20°C. Such a lowering of temperature from 30°C to 20°C reduces the natural rate of increase of the majority of noxious species of ~50%. The immediate cooling of harvested grain is generally feasible in all countries with a temperate or Mediterranean climate during the month following the harvest. Thus, in the United Kingdom cooling by aeration is used on 60% of the farms and in over 90% of the commercial stores. This proportion is also high in France (50% of commercial wheat and malting-barley storage facilities are equipped for cooling aeration assisted by a temperature monitoring system). It has been proven that grain aeration is also appropriate for warm countries such as Israel, Australia, and South USA provided that the air rh and moisture content of grain will be sufficiently low (e.g., 40% and 12%, respectively) to reduce the natural rate of increase of the main insect species. With an air-flow rate of $10\,m^3\,h^{-1}$, the total cumulative time of aeration is ~100–120 h, i.e., 10–15 nights at the rate of eight "favorable hours" per day. Automated control systems for automatic running of the aeration process are available to control fan operation, some of them being now associated to software packages in decision support systems. These systems can be used to perform the calculations and to produce an optimal design for fans, ducts, etc.

Heat disinfestation Temperature plays a major role in the number of physiological functions of insects that are "cold-blood" animals (poikilotherms). Heat was used to kill insects 80 years ago: temperature of 52–55°C maintained during 10–12 h were found effective for flour mill disinfestation. Several methods of heating grain in bulk are now available. A recent method is the use of fluidized-bed or spouted-bed heating, where heated air is used as the heat transfer medium. Wheat grain treated in a fluidized bed by hot air can be disinfested through the heating of grain to a temperature of 65°C that is maintained only a few minutes before a rapid cooling to ambient temperature. In these conditions of heat shock, it was found that this treatment does not adversely affect the viability, the moisture content, and the baking quality of wheat provided that grain is immediately cooled after the heating phase and that its moisture is at a normal level. At a temperature of 62–65°C inside the kernels, all developmental stages of insect internal feeders are killed. Several different approaches have been used to adapt heat rapid disinfestation for use with modern systems of grain storage. They all heat the grain during the conveyance. The final temperature to reach in the whole kernel required to kill insects is slightly above 60°C (62–65°C).

Fluidized-bed or spouted-bed heating is the first means of heat disinfestation that has been implemented at the practical stage ($150\,\mathrm{T\,h^{-1}}$). With the fluidized-bed process, cooling grain after heating is very easy with optimization of energy input by heat exchange between the hot and the cold parts of the equipment. Since heat disinfestation technology in a fluidized bed is compatible with the high grain transfer rates found in large storage facilities, a mathematical model of the process could be formulated. The prediction of the temperature at which grain is heated internally has been approached by simple asymptotic regressions using only the measurable variables: air inlet and outlet temperature, airflow velocity, and specific rate (volume of air per unit of grain mass). The simplification of the calculation for the model regression is as follows (eqn [1]):

$$1/t_{x\%} = T + C \quad \text{and} \quad T_{\max} - T = ab^{\exp[t_{x\%}]} \qquad [1]$$

where $t_{x\%}$ is time to give x% mortality, T is grain temperature (°C), $T_{\max}$ is air inlet temperature, and C, a, and b are constants.

In the recent years, a general modeling approach of heat and mass transfer in any system of grain drying, cooling, or aeration was obtained using numerical methods. From a starting point of a model describing moisture migration arising from natural convection currents in two-dimensional systems, an extension of the diffusion equation for moisture and water vapor through hygroscopic models has been proposed. Then, this model for the diffusion process was generalized to simulate moisture migration in grain bulks of arbitrary shapes. The actual model based on the finite element method allows the description of heat and moisture associated with both natural and forced convection aeration in arbitrary shaped grain bulks. Thus, real-time changes in moisture and temperature can be predicted enabling to detect air-flow conditions that may generate temperature or moisture accumulation or redistribution in the regions of the bin. This tool combining heat and moisture transfer can also be used to visualize, in two-dimensions, the effect of the spacing and the size of aeration ducts on the cooling or drying efficacy in all regions of the bin.

Microwave (MW) and Radiofrequency (RF) Heating

Infrared, radiofrequencies (RFs), microwaves (MWs), and light radiation are nonionizing electromagnetic waves that can be used for the direct transfer of radiant energy to solid matter such as grain (a dielectric material). Among these means, only RF and MW heating present an interest for heat disinfestation of food commodities, provided their qualities are not impaired by heating. Electromagnetic waves without ionizing effect such as MW and RF transfer energy from a source to a target without a need for an energy transfer fluid. In the case of MW and RF, their energy can be absorbed by inducing vibration of electrically charged particles within the matter, thus increasing temperature because of internal friction.

RF heating RF heating involves frequencies between 3 and 300 MHz, i.e., wavelength between 100 and 1 m, respectively. Commonly used frequencies for energetic applications in Industry, Science and Medicine (ISM use) have been fixed by regulations authorities at 13.56, 27.12, and 40.34 MHz. RF dielectric heating is accomplished with the product placed between two electrodes in an oven. Rapid heating of the exposed material is obtained in applying a high electrode voltage that induces a high alternative field intensity inside the material. Field intensities of $1.4-1.5\,kV\,cm^{-1}$ are currently applied for cereal grain disinfestation. The field intensity is quite uniform if the material is homogeneous in presentation between the electrodes.

MW heating MW heating involves a higher frequency range than RF heating, expanding from 300 MHz to more than 50 GHz. The main MW frequencies allowed for ISM applications are 434, 915, and 2450 MHz. The technology of MW was developed later than that of RF after the discovery of the magnetron and other MW sources in the years since the 1970s. MW heating is obtained with lower electric field intensities than RF heating. But, partly because of the lower wavelength of MW, attenuation with the depth of penetration in the material is high. The result is a certain heterogeneity if the material remains static under the MW source. To minimize this heterogeneity risk, the product is generally rotated or mixed during exposure to achieve a better homogeneity.

Even if interesting results have been obtained in disinfestation and, to some extent, in final-step dehydration of cereal grain either by RF or MW, this method has not been used in current practice for grain treatment because of the high capital cost of installations, the relatively high running costs for electric energy consumption (even if its transfer rate into heat is generally better than 60%), and the low product flow rate that can be disinfested by this treatment (pilot scale machines have reached $4\,T\,h^{-1}$ with an RF generator delivering 60 kW energetic electric field). There are many drawbacks for the current use of dielectric heating for grain disinfestation and yet this method has not been shown to be superior to air-based systems. Provided that there is a good monitoring of the heating process, the eventual damage to the end-use qualities of treated cereals at levels of temperature required to eliminate insects is limited and generally acceptable. These heat-sensitive qualities include bread-making quality of wheat, rice color and taste, and viability of malting barley and seeds.

Irradiation or Ionization

Irradiation represents either the exposure to γ-rays (radioactive isotopes) or to X-rays (accelerated electrons). Insects are not immediately killed after an irradiation but they are all sterilized at a low dose. Thus, irradiation of bulk grains may theoretically be used in order to eliminate insects provided that the presence of live but sterile arthropods is tolerable. Two different types of equipments correspond the two kinds of radiation: the radioactive sources (^{60}Co or ^{137}Cs) and the accelerated electrons emitted from a heated cathode. Gamma rays are penetrating deeply into the food products, whereas accelerated electrons have a limited depth of penetration limited to 2–5 cm. Consequently, the accelerated-electrons plant may only treat thin layer of the product conveyed under the irradiation "gun." A plant dedicated to the disinfestation of imported grain was used a long time ago (in the USSR) but is no longer operational. The technology of radioisotopes was tested in Indonesia recently for the disinfestation of bagged rice. This was observed an effective treatment against *S. oryzae* at a dose of 0.40 kGy.

Although there are internationally recognized agreements for the use of irradiation for disinfestation of a range of foodstuffs, including grain, there are public acceptance problems with irradiated food products. Consequently, the use of irradiation for grain disinfestation purposes is greatly affected by this negative perception of retailers and consumers.

Controlled Atmospheres

The process of controlled atmosphere (CA) disinfestation involves the modification or the replacement of intergranular atmospheric composition of grain bulks by inert gases CO_2, N_2, or their mixtures in association with a low level of residual O_2. The use of CA is an adaptation of the age-old principle of hermetic storage. In simple airtight or hermetic storage

systems, the progressive depletion of oxygen by the natural respiration of grain, microorganisms, and insects themselves can also be lethal for insects after long-term exposure. The lower the moisture content of grain, the longer the delay to kill the insects. An anaerobic atmosphere can be achieved quickly (several hours to several days) with the injection of inert atmospheres inside airtight grain storage structures. There are two different ways to eradicate insects in infested grain stored in an airtight enclosure by using CAs: the "high-CO_2" CA, often called "modified atmosphere" and the "low-O_2" CA.

High-CO_2 CA Adding carbon dioxide (more often under its gaseous form) to an airtight grain bin has an effect similar to that of fumigation. Carbon dioxide has a specific lethal effect on insects when its concentration is above 40% (v/v) in air. Atmospheres containing ~60% carbon dioxide rapidly kill stored-product insects. As an example, at a temperature of 26°C, ~4-day exposure would be sufficient to kill all stages of most stored-product insects. However, there are many drawbacks in using "high-CO_2" CA to control grain insects: the amount of CO_2 required to fumigate 1 ton (t) of grain is ~2 m^3, i.e., close to 4 kg of CO_2 in liquid form (to be compared to 2 g of phosphine gas). Carbon dioxide sorption on grain is important and may induce negative pressure in well-airtight enclosures. This phenomenon renders the practical management of CO_2 fumigation more difficult to achieve than a phosphine fumigation and the use of pressure safety valves is required.

Low-O_2 CA The oxygen depletion in an airtight enclosure may be principally achieved by adding oxygen-free gas such as pure nitrogen, or by adding low-oxygen content gas such as the output of an hydrocarbon burner (also called exothermic inert gas generator). In contrast to "high-CO_2" fumigation, it is considered that nitrogen is only active in producing a progressive hypoxia or anoxia without other particular effect on living organisms. Consequently, in pure nitrogen atmospheres the grain beetles can survive for more than 1 month at low-temperature levels of the grain during the winter season (e.g., 10–12°C). The rule of oxygen deficit being correlated with the killing dose–effect relationship has a classical exception with the weevil, *S. oryzae*, which is less tolerant to 1% O_2 residual concentration than to almost anaerobic atmospheres with only 0.1–0.2% residual oxygen. Pure nitrogen generation by a separation process of atmospheric nitrogen from air is now available with modern units useable on small capacity storages as it exists in cereal processing plants. The technology of generating nitrogen from air on-site (by separation and purification of the atmospheric nitrogen) is progressing rapidly and becoming cheaper.

Low-oxygen atmosphere can also be obtained by exothermic gas burners. Several such items of equipment were built in Australia, USA, and UK during the years 1980–95. No significant advantage could be proved between the use of a burner compared to the use of pure nitrogen neither in terms of insecticidal efficacy nor on an economical basis. There are very few grain stores equipped with fixed installations with either pure nitrogen or gas burners, except for certain high-grade cereals such as aromatic rice, or premium malting barley. The strategy that is most commonly used for CA is the permanent preservation under a low-O_2 atmosphere of grain in an airtight bin equipped with relief valves absorbing the differences in pressure in the airtight bin when temperature changes.

The future of CA fumigations CA treatments based on either nitrogen or carbon dioxide atmosphere storage provide technical alternatives to methyl bromide uses for disinfestation of bulk or bagged grain. But their use is constrained by the cost of the implementation of CO_2 fumigation or long-term generation of low-O_2 atmosphere by a burner or an atmospheric-nitrogen purifier. The slow speed of action of CA atmospheres is not really an inconvenience in tropical countries and several strategic reserves of cereals are preserved from deterioration by this technique in specific situations (e.g., in Indonesia or Singapore).

Other Miscellaneous Treatments

Mechanical Impact, Turning, and Pneumatic Conveying

During pneumatic conveying of grain in fluid-lift handling (e.g., when vessels and barges are out-loaded), the high-speed impaction of grains against the walls of the transportation ducts eliminates a significant proportion of adults and well-developed hidden stages of primary feeders. Adult stage of grain insects being particularly sensitive to a mechanical impact, this sensibility is exploited in impacting machines used on grain entering flour mills. This device eliminates a great part of infested grain and removes broken grains and their insect content by forced ventilation before the conditioning of grain prior to milling. In this way the content of flour and semolina in impurities of entomological origin is reduced to an acceptable level for the miller. This is not really a stored grain treatment but one can consider that it is the last tool available by the grain user to eliminate an insect infestation just before grain milling. Disinfestation of wheat grain prior to milling by impacting machines

("entoleter") has been routinely used for more than 20 years in the flour and semolina industries to destroy all insect stages.

Inert and Abrasive Dusts

For two decades, several inert dust formulations have been registered for structural treatment and to protect stored grain. Diatomaceous earth (DE) and silica aerogels (and their mixture) are used in several countries as an alternative to the use of chemical protectants, especially when grain is not treated with chemicals (e.g., organic grain or grain intended for uses in baby food). DE is classified as a "generally recognized as safe" (GRAS) food additive by the US Environmental Protection Agency. It provides a good protection against insect infestation in dry grain stored for a long term in flat bed stores. Liquid formulations of DE are used in Australia and North America for grain protection in sprays applied to the storage fabrics to minimize residual infestation in grain store buildings and to limit the migration of pests into the bulks of stored grain. DE is an effective protectant when applied to the entire grain mass at a dose of $200\,mg\,kg^{-1}$. However, DE on grain is also considered as poorly effective with grain at an elevated moisture content as it can be found in humid temperate countries (northern Europe, Canada, and northern Asia) where the moisture content of stored cereal grain can be as high as 15%. Problems associated to the use of DE in large-scale operations are: (1) machine abrasion; (2) a reduction in the bulk density (test weight), which is a criterion of grain quality used worldwide; (3) grain fluidity change; (4) decrease in qualities such as color and presence of foreign material; and (5) health hazards (respiratory disease hazard for the applicators).

Combined Methods

Physical methods can be used simultaneously or in sequence, especially if there are synergistic effects. For instance, low-O_2 and high-CO_2 (hypercarbic) atmospheres in airtight enclosures have a higher efficacy rate when temperature is elevated to levels that cause hyperactivity of target insects. Consequently, the reduction of time needed for disinfestation process is significant even for species that are rather concentration insensitive to carbon dioxide such as *Tribolium confusum*.

Decontamination of Spoiled Grain

Preliminary Considerations

Stored grain molds may grow in grain with an a_w level more than 0.65 (*see* **Stored Grain**: Physico-Chemical Treatment), i.e., for the majority of cereal grain, when moisture content is more than ~14.5% (wet basis). Some of the grain mold species produce mycotoxins which are potentially hazardous to man and animals. Mycotoxins are a worldwide important issue in terms of public health, agro-food industry concern, and economics. The optimum temperature for growth of stored grain molds is ~25–30°C, but some grow well at 35–37°C or above, like *Aspergillus* spp. Grains are contaminated by spores of storage fungi during harvest, transport, and handling operations. In storage, provided that temperature and moisture content (a_w) meet their minimum requirements, they germinate and fungal growth occurs. The rate of growth is correlated with the levels of a_w and temperature.

Mechanisms of Grain Spoilage

Mycotoxins are secondary metabolites of fungi. Many storage fungal species may produce mycotoxins. The most toxigenic storage fungi include members of the genera *Aspergillus* and *Penicillium*. Formation of mycotoxins is closely related to mold growth. Without mold growth, mycotoxin production will not occur. Competition between storage fungi influences mycotoxin production by the most hazardous toxigenic species such as *Aspergillus flavus* or *Penicillium verrucosum*, the species producing aflatoxin B1 and ochratoxin A, respectively. An infestation of stored grain by insects can also enhance the production of mycotoxins. The presence of molds on the grains does not mean the presence of mycotoxins but that the potential for mycotoxin production exists. However, the absence of storage fungi on grain stored on a long-term period does not guarantee that the grain is free of mycotoxins. The fungal growth can be related to the fungal biomass produced by storage molds in grain. The best criterion that can be used to quantify the fungal biomass produced by the storage microflora is the ergosterol content. Thus, ergosterol content is considered as a good biochemical marker of fungal growth and represents a permanent index of mold spoilage, with or without mycotoxin production, that persists with time.

Decontamination Methods

Once grain is contaminated by toxic fungi due to prevention measures not being applied or incorrectly applied, only a few practices are available. Any decontamination process has its own limitations, since the treated products must be health-safe from the chemicals used and their nutritive value should not be diminished. So, unless the contaminated grain batch is of considerable value for a potential user, the first recommendation with mycotoxin-contaminated

grain is its complete destruction. If the conditions for a decontamination of grain are favorable, it may be carried out in two different ways: (1) separation of the contaminated kernels from the sound grain, and (2) inactivation of mycotoxins by physical, chemical, or biological means. Mechanical automatic separation of heavily contaminated kernels with an abnormal dark color can be removed by specific photoelectric detection machine based on imaging and robotics (electronic color sorting). The screening and discarding of small shriveled kernels by density-based separation equipment may also significantly reduce the amounts of mycotoxins in grain because the most heavily infested kernels are less dense than the sound ones. Mycotoxins in contaminated grain may be detoxified or converted into a nontoxic derivative using a limited number of practices. Aflatoxin being the most dangerous mycotoxin, the majority of decontamination treatments preferentially affect this mycotoxin. Heating and cooking under pressure can destroy a great part of aflatoxin in grain but this process cannot be applied to whole grain intended for food uses. Detoxification of oilseed cakes and corn using ammonia is a marginal method. It may be useful only for the decontamination of cereal by-products such as bran (this grain tissue is the most heavily contaminated) extracted from contaminated grain and that need a decontamination before utilization for feed making. The ozone treatment combined with heating (100°C) has a potential to inactivate aflatoxin toxicity. Nevertheless, several hours of exposure are needed and this treatment may decrease protein efficiency ratio and available lysine (observed only on peanut meal).

Future Prospects of Stored Grain Preservation

Stored Grain Quality Maintenance

The quality maintenance of stored grain has traditionally been the responsibility of grain handlers who rely on measurements achieved on samples of grain or its milled products and on implicit knowledge gained through science, common sense, and job experience. Today, treatments achieved for quality preservation may be integrated into operational systems if they are to be effectively applied. This basic principle connects with the modern approach of integrated quality management (IQM). Integrated quality management of stored grain can be defined as the acceptable use of practicable treatments to minimize, cost-effectively, the losses and damages caused by deteriorative forces (insects, mites, and microorganisms), or the consequences of a poor control of grain condition (temperature manipulation, a_w control by drying, dockage level, insect infestation). Thus, decision support systems (DSSs) are indispensable to solve stored grain preservation issues that require experience, knowledge, judgment, as well as a knowledge base to explain the complex deterioration processes occurring in stored grain bulks. DSSs are considered valuable support to promote the implementation of the IQM strategy at the practical level.

The Potentialities of Computer-Aided Decision Systems

The potentialities of computer-aided decision systems have continuously evolved since their first application to stored grain pest management. Actually, the DSSs are considered as very useful tools for grain handlers to take optimal management decisions. Several DSSs are in use for many purposes in stored grain management: (1) diagnosis of grain condition; (2) prediction of risks for long-term storage of grain lots; (3) as an aid in insect identification; (4) to monitor stored grain condition and support problem solving; (5) to support the implementation of drying or cooling operations; and (6) to predict the storability prior to storage. Until recently, the majority of the systems under current use were devoted to pest management and to the training and education of extension workers. A new approach of total quality management of stored grain was tackled only recently. It is based on the computing of an array of causal relations between all variables of the stored grain ecosystem (whatever their nature and the form of causal relation). This approach consists in combining: (1) the models of complex interactions between control and state variables of the stored-grain "ecosystem" and (2) the human experts' subjective knowledge on the changes that will occur in grain quality criteria during storage in constant conditions. The safe storage period (grain "storability") as well as the effects of different treatments (such as cooling, drying, separation of impurities, insecticide admixture, etc.) may be predicted by such a knowledge-based system. For each described situation (grain initial condition), an output is delivered under the form of storage options susceptible to increase the safe storage period. The data collected on stored grain condition by sensors and probes (temperature, a_w or moisture content and storage time) can also be computed to see if the stored grain observed quality state is identical to the prediction by the DSSs at any time during storage. The remote control of the drying or cooling processes may also be entirely assumed by DSSs. Tools for automatic detection and identification of insect species at very low population density levels are now available to predict storage–insect population dynamics.

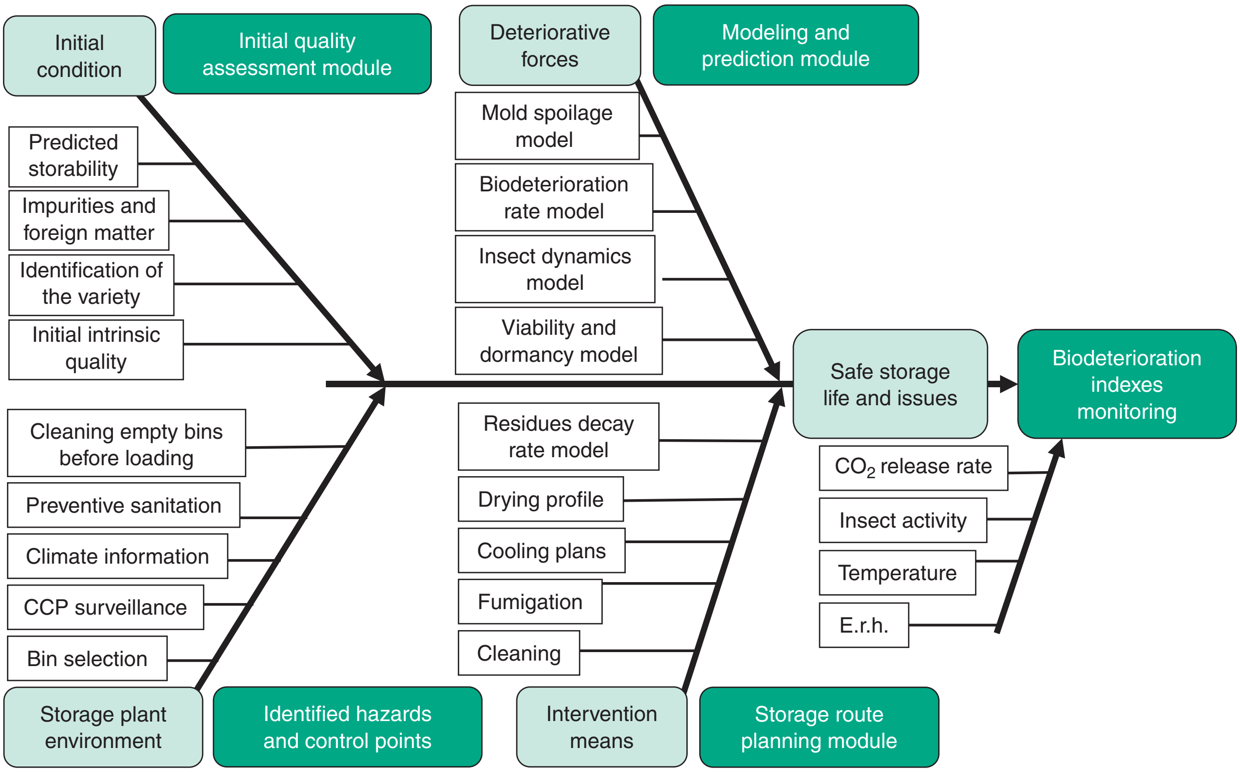

Figure 2 Decision-tree diagram associated to the knowledge base of a decision support system enabling the integrated management of quality criteria of stored malting barley in relation to storage time, intervention means, and grain condition.

The Scientific Approach to Grain-Quality Retention

The scientific approach to grain quality retention during storage can entirely refer to computer-assisted DSSs. Thus, such artificial intelligence tools enable the grain handler: (1) to understand the causes and economical consequences of quality changes in grain bulks; (2) to forecast quality changes; (3) to provide support for problem solving; and (4) to propose optimal storage strategies (Figure 2). The methodology already applied for malting-barley quality computation should be expanded to quality management and control of any type of cereal grain in the near future.

Physico-Chemical Treatment

F Fleurat-Lessard, INRA, Villenave D'Ornon, France

Introduction

The storage of cereal grains is achieved for extended periods of time in order to supply the domestic and export needs. The storage period may last several months to a year or even more when grain is stored for market regulation objectives or as strategic reserve. At a central position along the processing chain, the storage stage has to play three essential roles: (1) the assessment of the quality of each grain load delivered by the farmers in order to identify quality grades; (2) the preservation of original properties and composition of freshly harvested grain; and (3) the permanent supply of the first processing industries with homogeneous grain batches of a specific quality grade.

Postharvest losses of grain are a significant factor in the world food supply and may represent as much as 5–10% of the world production of cereal grains and oilseeds. On a qualitative basis, there is a constant risk of grain quality deterioration in storage. The quality of grain is specified with different attributes closely related to the making of a specific end product. It can be defined as the combination of an intrinsic and an extrinsic component with complex relationships. The intrinsic component of grain quality may be considered as both the initial condition and the biochemical composition of grain at the harvest (Figure 1). The extrinsic component – which includes the soundness, the purity, the sanitary, and the safety condition – is dependent on the action of deterioration factors. The two major biological causes of deterioration of properties and quality of stored grain are microorganisms (storage fungi) and invertebrate pests (insects and mites).

The deterioration of stored grain quality being irreversible, the prevention of quality losses is of prime importance for any grain store manager. To face the storage issues, he disposes of a range of equipment, tools, materials, and techniques to prevent (or reduce) the grain quality deterioration process. The stored grain treatment includes the elimination or the inhibition of the main causes of loss such as infestation by insects or mites, and contamination by microorganisms. However, minor causes of quality losses such as grain respiration, gradual deterioration of viability, nutritive quality, and end-use properties are also concerned by preventive actions. The preservation of stored grain from adverse storage conditions that may endanger its marketing value depends on different means that can be considered either preventive or corrective. The preventive means include cleaning, drying, aeration, cooling, pest control treatment, kernel breakage prevention, and controlled atmosphere storage. The corrective actions have rather recourse to quick-action treatments such as high flow-rate cleaning, fluidized-bed drying, temperature shock, fumigation, and some other grain sanitation treatments. This review of the means of stored grain preservation complements the previous works dealing with good storage practices of grain stocks that have been published in books listed under the Further Reading section.

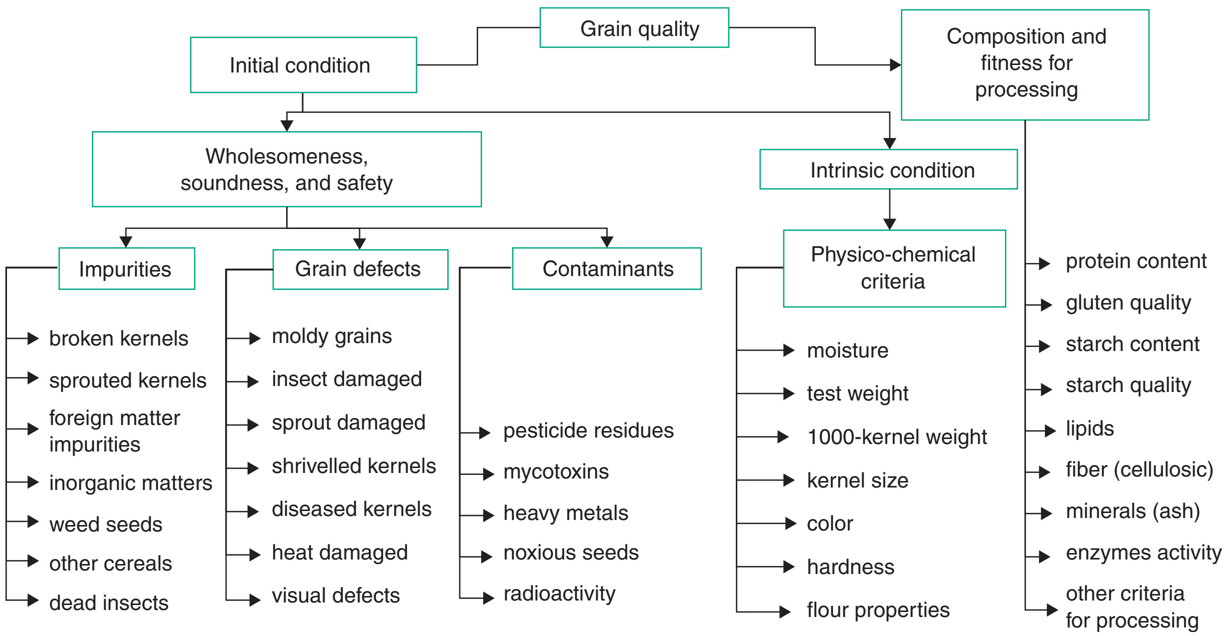

Figure 1 Basic criteria and parameters involved in the definition of grain commercial quality – four components are identified: intrinsic and physico-chemical condition; sanitary and safety condition; biochemical composition and nutritional value; and properties for processing. (Adapted from Fleurat-Lessard 2002.)

Grain Cleaning

Cleaning grain is usually done before storage of grain lots in bins or granaries. Freshly harvested grain contains a small proportion of impurities, also called "dockage." Dockage components include small or large seeds of weeds or other grains, chaff, straw, dust, soil pellets, small stones and boulders, cracked kernels, and other trash (*see* Contaminants of Grain). In other respects, harvested grain may contain shrivelled kernels, smaller than those of healthy grain and being in most cases heavily contaminated by pathogen fungi and their related mycotoxins. A maximum percentage of impurities is acceptable in grain trade, according to fluctuations of the respective limits for each kind of impurities fixed by each country regulations (*see* Defects of Cereal Grain). When this limit is exceeded, some quality criteria are affected (e.g., the test weight). Moreover, the presence of a significant amount of larger-sized impurities such as ear fragments, plant stalks, green weeds parts, grain husks, and chaff, etc., represent a serious risk for safe storage because they are a source of microbiological spoilage and lead to favorable conditions of multiplication for insects and mites. In the case of high percentage of wet impurities, grain heating may start in some parts of the grain bulk a short time after binning (humid hot spots). In addition, these regions with heated grains are liable to become compact enough to disrupt airflow distribution and hinder an eventual beneficial effect of drying or cooling later operations. Thus, the grain cleaning through the separation of a significant amount of impurities may improve grain condition before storage.

Grain cleaning operation can be carried out with a large range of equipment, ranging from the simple sieves used in developing countries to remove light impurities (thanks to the wind) to very sophisticated high-speed industrial equipment found in grain terminal elevators. Some of these high-flow-rate cleaners may clean 10–12 t of grain per hour with a work input of 1 kWh.

Some other cleaning equipment combines grain cleaning and calibrating operations. It has a much lower output than specific cleaning machines and it is mainly used by the seed-producing companies before conditioning perfectly cleaned and calibrated seed grains. Winnowing machines can also be included in grain cleaning equipment even if they are mainly used to clean the part of the grain harvest kept by small farmers as their own seed reserves.

From an economical point of view, the financial profitability of removing dockage and foreign material of grain devoted to export depends on the initial dockage level. Some export markets will pay a premium for dockage-free grain while other markets do not. Consequently, grain cleaning is generally not practiced in all cereal-producing and -exporting countries. In USA and France, grain operators have little economic incentive to provide dockage-free

grain. The delivery of cleaned grain is marginally profitable in Australia, a cereal exporting country that supports a policy of exporting high-quality grain. In Australia, the grain cleaning costs are deducted by the grain handling company from the value of the raw grain delivered by the farmers to commercial grain stores.

In-Bin Drying

Preliminary Considerations

Seeds being hygroscopic, grain either absorbs moisture from the environment (under high relative humidity (rh) conditions) or loses moisture (under low rh conditions). This relationship is generally represented graphically by two typical curves, respectively, when grain is adsorbing or desorbing moisture. These curves represent the correlation between the surrounding air rh and the water activity (a_w) potential in the kernel at a constant temperature (so-called isothermal sorption–desorption–equilibrium curves). When this thermodynamic equilibrium is established, the temperature and pressure being constant and equal in the two phases (gaseous atmosphere and grain), the grain a_w can be numerically identified with the ratio of the partial pressure of water in grain surrounding atmosphere (in "empty" space of the grain mass) (eqn [1]):

$$a_w = \frac{\text{equilibrium rh } (\%)}{100} \qquad [1]$$

In this equilibrium condition, there is a close relation between the moisture content of the grain, and the a_w (or the rh inside the grain bulk). Consequently, grain a_w can be related to the moisture content of grain by mathematical models. Numerous mathematical models of these sorption–desorption equilibrium curves have been built up in dependence with the temperature level for almost any type of seed or food matrix. Several researchers have regularly refined the equations that are now available for the majority of cereals and are accurate enough to be used for the monitoring of aeration or moisture migration changes in a stored grain bulk through rh sensors (eqns [2a] and [2b]):

$$\text{rh} = \exp\left[-\frac{C1}{T + C2}\exp(-C3M)\right] \qquad [2a]$$

$$M = \frac{1}{-C3}\ln\left[\frac{(T + C2)\ln(\text{rh})}{-C1}\right] \qquad [2b]$$

where rh is the relative humidity, M the moisture content, T the temperature, and $C1$, $C2$, $C3$ the coefficients.

The modified Chung–Pfost eqn [2a] gives a good fit with experimental sorption curve of cereal grain, especially for wheat and it can be used for the accurate conversion of moisture content into grain a_w for several cereals.

Moisture Content and Allowable Safe Storage Times

The importance of water in grain can be deduced directly from the sorption curve. From a critical a_w corresponding to the end of the linear portion of the desorption curve (Figure 2), a less tightly bound water appears that becomes available for the feeding biodeterioration processes. Thus, above a limit of a_w in grain the respiration becomes active. Consequently, the grain moisture content (or the a_w) is the most important factor determining the intensity of grain respiration. The heat produced by the respiration of organisms living in the grain bulk increases the temperature of the grain that indirectly favored the fungal growth. Grain respiration results from the aerobic consumption of complex carbohydrates (starch) by living organisms. This oxidation of energetic nutrients of grain also generates liquid water (eqn [3]):

$$C_6H_{12}O_6 + 6O_2 \longrightarrow 6CO_2 + 6H_2O + 2817\,\text{kJ} \qquad [3]$$

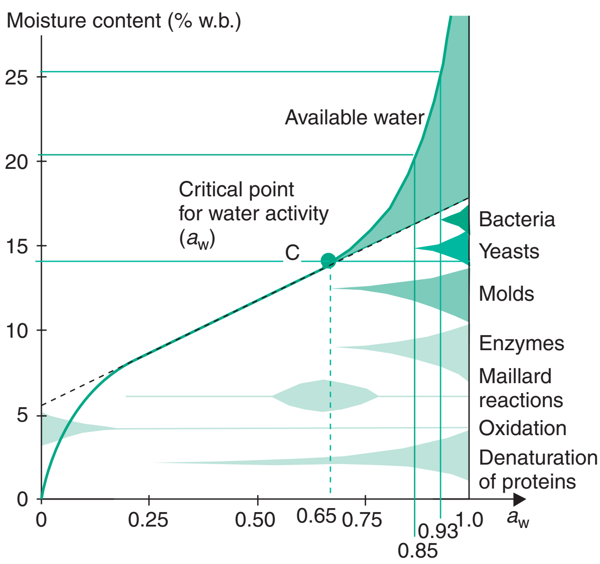

Figure 2 Grain desorption curve (wheat at 25°C) focusing on the zone in which water adsorbed in grain becomes available to support various processes of quality deterioration within specific limits of grain moisture content and water activity level. (Reproduced with permission from Multon JL (ed.) (1988) *Preservation and Storage of Grains, Seeds and Their By-Products*. New York: Lavoisier Tec and Doc. © Technique et Documentation.)

In airtight storage, when carbon dioxide level exceeds 10% and the oxygen levels falls down below 1%, the respiration process is inhibited and the anaerobic fermentation that occurs produces less heat (eqn [4]):

$$C_6H_{12}O_6 \longrightarrow 2C_2H_5OH + 2CO_2 + 209\,\mathrm{kJ} \qquad [4]$$

In addition, nonuniform temperatures in the grain bulk generate air convection currents and lead to moisture migration, especially when large changes in external air temperature occur. These moisture migrations may induce the "top crusting" phenomenon that develops at or near the grain surface in metallic bins or in flat storage during the grain natural cooling (Figure 3).

Among the various living organisms in the stored grain ecosystem, the storage fungi represent the major causes of deterioration in grain and seeds. The main deleterious effects of fungi on stored grain quality are: (1) decrease in germinability; (2) induction of changes in kernel color and external aspect; (3) induction of hot spots where grain is heating; (4) inducing a mustiness odor that may be detectable by smelling; (5) induction of various biochemical changes; (6) production of mycotoxins that, if consumed, may be injurious to man and to animals; and (7) loss in weight and decrease of specific weight.

The water activity (a_w) of grains is closely related with the growth and the metabolic rate of storage molds. Therefore, the safe storage life of a grain bulk is dependent on the level of moisture content of grain at the beginning of storage. However,

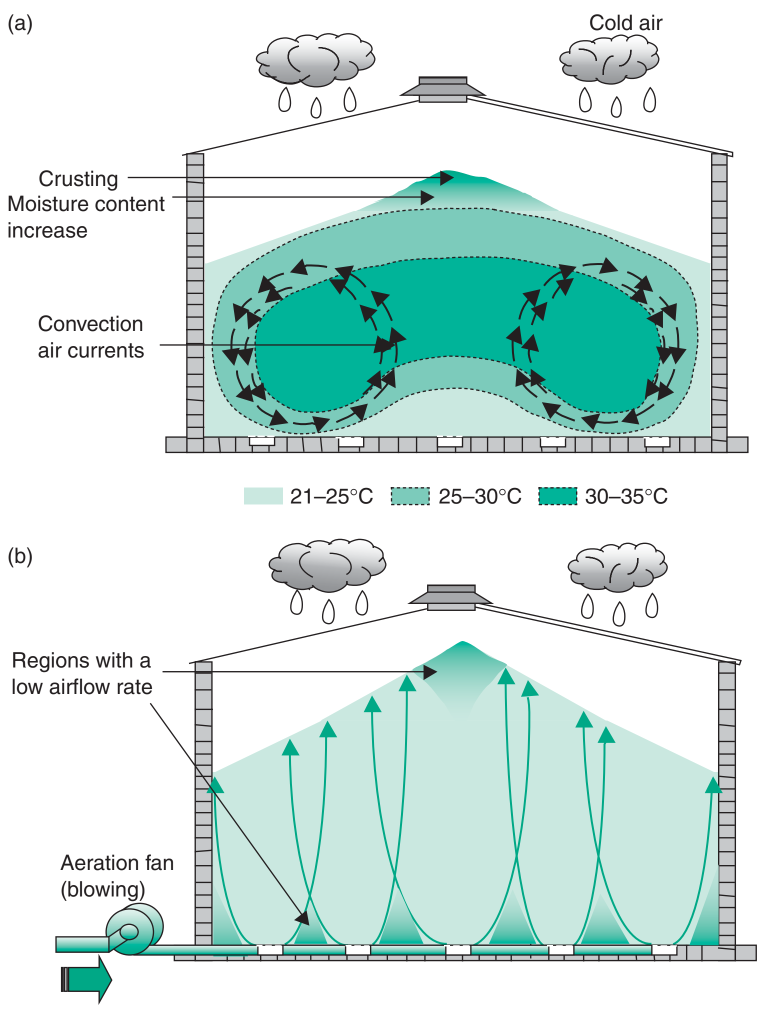

Figure 3 (a) Moisture migration pattern in freshly harvested grain stored during several months in a nonaerated metallic bin when outdoor temperature is lower than grain temperature showing the "surface crusting" phenomenon (adapted from various sources). (b) Grain cooling of a flat-bed grain bulk by a blowing system of aeration with multiple longitudinal air ducts – progress in cooling and observed distribution of cooled and less-cooled regions of the bulk.

below the a_w threshold of "available" water presence, both the germination of fungal spores and the growth of storage fungi are inhibited. Today, the different thresholds of a_w allowing the development of fungal species that may grow in stored grain are well known, especially for the species that are potential mycotoxin producers such as *Aspergillus flavus*, *A. ochraceus*, *Penicillium cyclopium*, *P. verrucosum*, and *P. viridicatum* (Table 1). This knowledge has been regularly refined, permitting the development of predictive models of "safe storage life" of stored grain from indexes of deterioration such as the decrease in germinability or from composite indexes combining relevant quality criteria. These quantitative models take into account the original quality of grain and the expected storage conditions (temperature and moisture). These models permit the prediction of the quality status of stored grain at any stage or the determination of the time left before to reach the minimum acceptable level of quality. The provision of models to predict safe storage life of stored grain offers the possibility of maximizing and guaranteeing market value in terms of grain-specific utilization by the processor or the consumer. As an example, an equation applicable to the determination of the safe storage period for malting barley, before the limit of 95% viability level is reached, was recently validated (eqn [5]):

$$M_t = \frac{\ln(35/T)}{\exp(C4 + C5 \times a_w)} \qquad [5]$$

where M_t is the safe storage time, T the temperature, and $C4$ and $C5$ the coefficients of the equation, variable with the type of cereal (e.g., for malting barley, $C4 = -21.22$ and $C5 = 20.33$).

In generalizing the previous equation for malting barley, a model of calculation of sorption equilibrium was derived. It can be useful in monitoring moisture content changes during drying or aeration operations. This predictive model may be included in the knowledge base of software packages aimed at the management of stored grain treatment or they can also be used as prediction tools (Figure 4).

To properly stored grain, both the grain moisture content and the temperature level must be compatible with the expected period of time the grain will be stored and with the grain intended use. The commercial upper limit of moisture content corresponds generally to critical moisture level for grain respiration activity, lowered with a safety margin of ~2%. Thus, the lower limit of grain moisture content allowing the growth of storage molds at 20°C in malting barley is 16.2% and the limit recommended for safe storage conditions was recently fixed at 14% in Europe. The recommended moisture contents for stored grain are listed in Table 2 in the two common situations: local short-term storage (less than 6 months) and regional or terminal long-term storage (for more than 6 months).

The Main Objectives of Drying

In regions where the climate is humid, mature grain is harvested at moisture content levels incompatible

Table 1 List of storage (xerophilic) fungi harmful for stored cereal grain quality and the associated mycotoxin production (when it exists)

Fungus species	*Mycotoxins*	*Grains more often affected*	*Minimal a_w for growth*	*Corresponding grain moisture at 20°C*
Scopulariopsis brevicaulis		Oilseeds/rice/peanuts	0.90	22.5

with safe storage for a long period of time. The removal of the excess of moisture from grain can be achieved by grain drying. Thus, the prime objective of grain drying involves reducing the moisture content in harvested grain in order to minimize mold-spoilage hazard during long-term storage. Thus, drying grain to the equilibrium with an air rh of less than 70% is a necessary prerequisite for safe storage. Additionally, low moisture content levels are less favorable conditions for the growth and buildup of populations of insects and mites.

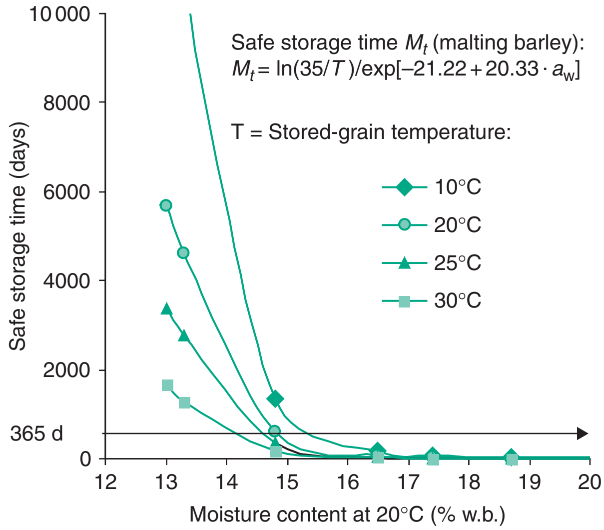

Figure 4 Quantitative model predicting the safe storage life of malting barley (95% germinability) in relation to moisture content and temperature in stored grain (constant conditions).

Table 2 Maximum recommended moisture contents of various grains for short-term (6 months) or long-term (more than 6 months) storage

Grain-Drying Technologies

There are two different grain-drying techniques.

1. High-temperature drying which is performed from specialized equipment with a high grain-flow rate and mainly devoted to the drying of wet grain that cannot be stored in its initial condition at the harvest (maize, sorghum, paddy, oilseeds, and all small-grain cereals grown under wet climates). This method involves an initial high capital investment and high running costs for a drying operation achieved in a few hours in continuous-flow grain dryers.
2. Low-temperature or natural air drying, which concerns grain batches needing a moderate reduction of moisture content at the harvest. This kind of drying can be carried out with minimal specific equipment in grain stored in bins specifically equipped for drying purpose. The complete drying can last over a period of several weeks.

Only the second type of drying corresponding to "in-bin" grain drying will be described below.

In-Bin Grain Drying in Practice

Drying has two basic stages: (1) diffusion of internal moisture to the surface of the kernel and (2) removal of external moisture by an airflow around the kernel. Water-vapor pressure is increased inside the kernel which causes moisture to diffuse through the micropores of the seed pericarp layers. The grain temperature is related to the rate of moisture diffusion and therefore can be monitored and controlled in order not to exceed a maximum rate of diffusion that could produce grain damage. The rate of evaporation of external moisture is also dependent on the air temperature (at a fixed airflow). These two stages are in constant interaction and in unstable equilibrium. The drying rate is also affected by atmospheric conditions. In this situation of complex interactions between several variables, the initial setting of the parameters of the drying system cannot be predicted, and it is necessary to test the drying process with several batches of grain before determining the exact setting of the dryer on a specific storage site. The main parameters that must be taken into account in determining a grain-dryer setting are given as follows:

1. the evaporation capacity, which is a fundamental characteristic of any dryer (expressed in kilogram of water evaporated per hour: $\mathrm{kg\,h^{-1}}$);
2. the heating capacity, which is the quantity of heat produced by the dryer per hour ($\mathrm{kJ\,h^{-1}}$);
3. the drying yield, which is the percentage of effectively used drying power (corresponding to the

amount of water removed from grain) on the delivered power (energy consumed by the dryer);
4. the net calorific power of the dryer burner fuel, which is the heat quantity effectively delivered by the combustion of fuel (in $\mathrm{kJ\,m^{-3}}$);
5. the specific airflow rate through the grain mass which is the rate of the airflow per unit of grain mass (in $\mathrm{m^3\,h^{-1}}$ of air per $\mathrm{m^3}$ of grain); and
6. the specific heat consumption, which represents the heat quantity required for the evaporation of 1 kg of grain water. This value is closely related to the fuel consumption and is generally minimized by the grain-dryer manufacturer.

In addition, the evaporation capacity and the rate of dried grain produced per hour in defined conditions of initial moisture content of grain and blown air temperature level in the dryer are also taken into account.

In static dryers operating in a bin equipped with air ducts in the bottom or with a perforated floor, a close relation between the temperature of the air blown through the grain mass and the renewal rate of the air per unit of grain bulk volume must be respected in order to obtain a homogeneous profile of moisture content throughout the dried grain bulk.

Different types of static driers for stored grain are used in developed countries, especially at the farm level. The original in-bin high-temperature drying system is initially loaded with a batch of grain, which remains in the bin until the drying operation is achieved. During the first phase of drying, grain is heated and in the second phase grain is cooled by ambient air aeration in order to recover its initial temperature. During the drying/hot-air stage, the grain mass is crossed from bottom to top or from side to side by the "drying front." The eventual heterogeneity that may occur at the end of the drying process, when the drying front comes out the grain mass, is generally limited by mechanical stirring-up devices. In these systems, the air temperature is $\sim$50–60°C with a specific flow rate of $140\,\mathrm{m^3\,h^{-1}}$ of air per $\mathrm{m^3}$ of grain. During the drying operation, the grain of the bottom of the bulk is systematically drawn up at the top of the bulk by several vertical augers (Archimedean screw).

Another type of dryer built on the same principle provides a continuous grain flow within the drying bin. The dried layer of grain at the bottom is regularly extracted and moist grain is automatically added above the previous batch. In this configuration, the maximum thickness of the grain layer should be limited at 2–4 m, and the specific airflow rate at $300\,\mathrm{m^3\,h^{-1}}$ of air per $\mathrm{m^3}$ of grain, and air temperature can be set in the range 40–80°C, depending on the sensibility to heat injury of the processed grain.

Storage bins equipped with aeration systems can also be used in a specific process of drying called "dryeration." In this process, the grain is partly dried in a conventional continuous-flow dryer and then the partially dried batch of warm grain is aerated by ambient air in a resting bin during 2 weeks. This type of process is more economical and involves less labor input compared to a continuous-flow drier. However, the aeration of semi-dry grain requires specific aeration equipment. The specific flow rate must be maintained between 40 and $60\,\mathrm{m^3\,h^{-1}}$ of air per $\mathrm{m^3}$ of grain. Nevertheless, after the cooling and the end of the drying operation, the grain must be transferred in a long-term storage bin. These additional handlings of the grain batch may increase the amount of broken grain. The dryeration system is used only to dry wet grain at the harvest such as maize or sunflower seeds. There is a risk for a slight loss of dry matter during the aeration of warm grain (coming from the drier at a temperature levels of 50–60°C) and the cooling bin must be equipped with air extraction fans in the headspace above the grain mass in order to minimize the water condensation problems that may occur in any metallic bin.

The temperature level reached by grain during conventional or dryeration drying, which is more than 60°C, is lethal for most of the hidden stages of insect primary feeders that may be present inside maize, rice, or sorghum kernels at harvest. This disinfestation effect of heating grain during the drying process will be developed further with the heat-shock treatment.

The drying of maize cobs in a bin equipped with an inclined perforated floor has also been used in order to limit the development of fungal microflora on humid grain (especially maize and sorghum) and the consecutive production of various mycotoxins, either produced by field fungi (when growing conditions remaining favorable for the field microflora) or by the most competitive strains of storage molds (on partially dried grain).

Aeration and Cooling

Preliminary Considerations

The stored grain bulk is slowly influenced by environmental temperature due to its low thermal conductivity. Although temperature has little direct influence on grain condition, it greatly influences the development of insect and mites and microorganisms, and it affects the viability of seeds. The first objective of aeration is to reduce the temperature of grain at the start of the

storage period. Harvested grain typically comes into store at average outside temperature in summer, i.e., often above 25°C or more in Mediterranean or subtropical cropping areas. At such temperature levels even dry grain is at risk from insects and moisture migration within regions of the grain bulk. Grains harvested or dried at commercial moisture levels (12–14% moisture) and at temperature levels as high as 25–35°C cannot be preserved during a long period of time if they are not cooled at lower temperature levels, thereby inhibiting quality-deterioration processes. Moreover, the viability of seeds decreases rapidly in a few weeks in grain stored at 30°C or more.

Purpose and Benefit of Aeration

Aeration is the process of forcing air through grain to reduce its temperature. The main beneficial effects of grain cooling are given in the following:

1. preservation of the technological properties of stored grain at a grade level as close as possible as its initial grade at the harvest time (e.g., baking quality of wheat, viability of malting barley);
2. limitation of the moisture migration phenomenon in bulked grain storage and related mold development, which is the principal cause of damage to several grain quality parameters (e.g., reduction of seeds viability and increase in fat acidity);
3. reduction of the dry matter loss consecutive to the natural respiration of grains remaining active in high-temperature conditions. The associated risks of release of metabolic water and of hot spot forming are also reduced; and
4. prevention of the insect multiplication at a high rate of increase when temperature can be lowered below 12–14°C, the level at which the rate of increase of the most cold-tolerant species falls to zero.

The use of cooling aeration was first developed to reduce problems of moisture translocation with warm grain when stored in metallic bins. But, the potential of cooling grain by forced air aeration is currently used to combat arthropods as pest and to unify temperatures, thus preventing moisture migration and hot spot formation. The theoretical basis of temperature transfer to grain by aeration either with ambient or with refrigerated air has been investigated by a large number of authors since the 1980s that lead to the production of many reference reviews. More recently, several simulation models for temperature migration during a cooling/aeration process have been produced and they may become useful supports for automatic control of aeration and for an adequate design of air ducts and ventilator characteristics. Heat and moisture migration within regions of an aerated grain bulk can now be visualized in real time for each distance element of the bulk and at each time increment using finite element/difference methods. With modern computers, real-time calculation can be carried out fast enough to produce moving images.

Practical Implementation of Cooling Aeration

Stored grain aeration requires the provision of an air-exhaust ventilator associated to an adequate storage bin design. Grain bins devoted to aeration have to be equipped with perforated ducting on the floor through which air is blown into (or sucked through) the grain. The design and the dimension of the ducts, as well as the optimal characteristics of the ventilator are described in previous reviews. The air-feeding network (pipes and ducts) has to be properly calculated to minimize the pressure drop for an appropriate airflow rate ($5-15\,m^3\,h^{-1}\,m^{-3}$). A centrifugal fan is not appropriate for aeration of bin higher than 15 m, when fan static pressure exceeds 2 kPa (e.g., for wheat aerated in a 15 m high bin with an airflow rate of $10\,m^3\,h^{-1}\,m^{-3}$). When air is blown, the fan compresses and heats the cooling air (e.g., 2°C in the conditions of the previous example). This disadvantage is overcome when air is sucked from top to bottom by a fan at ground level.

When air is forced through the grain mass, it carries both a "cooling front" and a "moisture front." The temperature front moves rapidly, this speed being governed by the rate of airflow and the temperature of the aeration air. The cooling power of this front is rather independent of the initial temperature of the grain. In well-designed aeration installations, the speed of the moisture front is so slow that wetting problems seldom occur or they are localized in very small regions of the grain bulk.

There are many storage situations where ambient air conditions are not sufficient to cool grain. Nevertheless, aeration with refrigerated air achieves much lower temperatures when ambient conditions are warm. In warm climates, or when very warm grain (35–40°C) is stored immediately after the harvest, aeration with ambient air may not be sufficient to control fungi on moist grain, or to preserve the germination capacity and quality of stored grain. Grain chilling through refrigerated air ventilation is regarded as an expensive method if used only for insect control purposes, but it can be justified for storage of fragile grains such as malting barley and seed grains in hot conditions, when retention of viability is required. Refrigerated air units for chilling grain have been developed to enable aeration to be carried out in summer for temperate regions of Europe and North

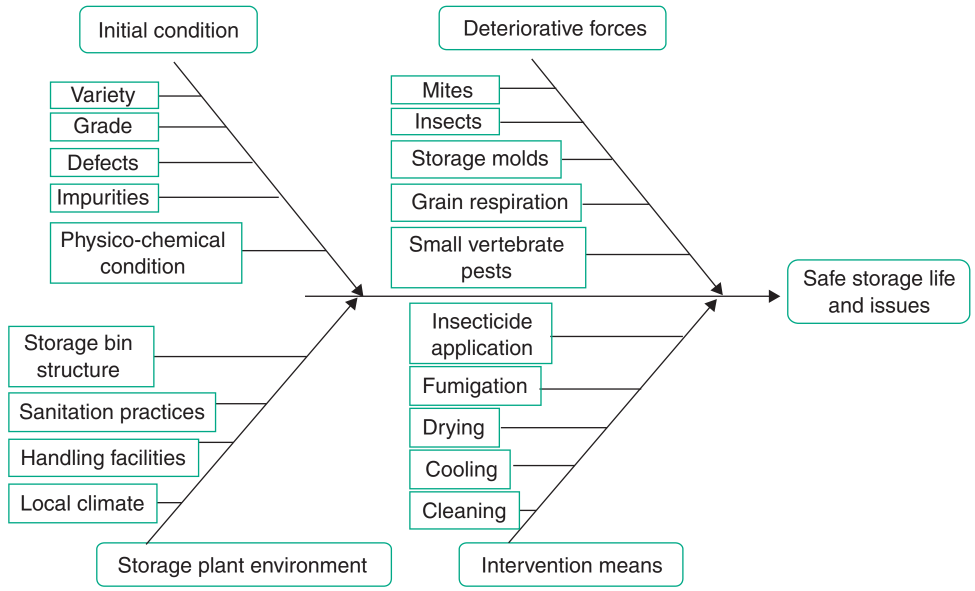

Figure 5 Cause-and-effect diagram (Ishikawa fishbone chart) applied to the stored-grain ecosystem: description of the changes with time and storage conditions of quality criteria of malting barley.

America and in tropical climates where aeration with ambient air is totally impractical.

Other Miscellaneous Treatments

Mechanical Impact, Turning, and Pneumatic Conveying

When grain is warming in a bin, it can be turned (e.g., out-loaded and returned to storage) to help maintain a homogeneous temperature and, if any, to eliminate the "hot spots" or "caked grain" during turning bulk grain from one bin to another. However, at each time grain is moved, there may be a loss due to additional breakage. In addition, when "hot spots" are effectively formed, the fungal spoilage and contaminated grain with mycotoxins can be mixed with the sound part of the grain batch during moving. There is only a slight decrease in the average temperature of grain during turning from bin to bin.

Limitation of Kernel Breakage

The free fall of grain during empty bin filling or throwing grain through grain thrower in loading vessel holds or flat-bed storage compartments presents some serious risks of kernel breakage. This increase of the percentage of broken kernels, a part of the dockage, can lower the grade and the commercial value of an entire grain batch. The maximum breakage is obtained from drops on a concrete surface inclined 45°, and minimum breakage is observed from drops onto a grain surface. Grain handling through a bucket elevator is also a source of significant breakage. Reducing grain velocity and impact by different systems reduces physical damage. Drops of less than 12 m, or on a layer of grain reduces the breakage. Increasing the size of the grain stream is also beneficial. Reduced bin height, additional equipment to reduce velocity, and slower handling of grain can reduce kernel breakage hazards.

Future Prospects

The grain bulk is an ecosystem and, in most cases, stored grain treatments are used as preventive methods in order to prevent the occurrence of biodeterioration processes during the expected storage time (Figure 5). The stored grain quality management more often requires the combination of different methods and approaches to give optimal results. This combination needs to take into account the wholeness of the user's requirements in order to meet his demand, e.g., for residue-free grain or viability-guaranteed seeds after a long storage time. Recently, a qualitative reasoning approach was developed to support storage treatments combination and their logical chaining (*see* **Stored Grain**: Pest Management). This new approach should allow the grain handlers to more easily fulfill the buyer's quality expectations and to minimize the costs of stored grain preservation.

SUNFLOWER

T J Gulya, Northern Crop Science Laboratory, Fargo, ND, USA

Published by Elsevier Ltd.

Overview

Sunflower (*Helianthus annuus*) is grown as an oilseed crop worldwide in temperate and subtropical climates. Among oilseeds, sunflower generally ranks fifth behind soybeans, rapeseed, cottonseed, and peanuts, with an average annual world production of 21–27 million metric tons (Mt) (Table 1). Unlike soybean, sunflower is primarily an oil crop, with high protein meal being a by-product. Sunflower is grown on every continent, with Argentina, the former USSR, Eastern Europe, the European Union, and the United States being the largest producers (Table 2). US production accounts for 7–9% of the world output. Nutritionally, sunflower oil has the greater proportion of the unsaturated fatty acids (oleic, linoleic, linolenic), than many other vegetable oils, especially in the recently developed high oleic content NuSun™ varieties (Table 3).

History

Sunflower was domesticated by Native Americans in the eastern US ~3000 BC. They used the seeds directly as food and crudely extracted the oil. Native Americans had selected a tall, single-headed variety by the time European explorers reached North America in the sixteenth century. While sunflower was not the staple that the "Three Sisters" (maize, beans, and squash) were, it, nonetheless, was cultivated by many tribes from eastern North America through the Midwest and as far as northern Mexico. The Native American also used sunflower hulls as a source of dye, leaves for herbal medicines, and pollen in religious ceremonies.

Historical records indicate that Spanish were the first to introduce sunflower to Europe in the early 1500s. Sunflower was initially grown as an ornamental plant. Early English and French explorers also introduced it to their respective countries. From western Europe, sunflower spread along the trade routes to Egypt, Afghanistan, India, China, and Russia. By the early 1700s, sunflower seeds were eaten as a snack, and in 1716, the first patent for the use of sunflower oil (for industrial purposes) was filed in England. The most significant

boost for sunflower as a crop, however, came from the Russian Orthodox Church. Lenten regulations prohibited the consumption of many oily foods, but since sunflower was not specifically listed, the seed and oil became a staple diet item in Russia.

Efforts by Russian scientists led to significant crop improvements with oil contents soon exceeding 40%. While sunflower was grown throughout western and eastern Europe, Russia historically was the largest producer with production in excess of 3 million hectares (Mha) in the early twentieth century, compared to 1.5 Mha for the rest of Europe. Russian immigrants are credited with introducing sunflower to North America. In fact, the open-pollinated variety "Russian Mammoth," still sold by garden seed firms, traces its lineage back to the same-named variety initially introduced in the 1880s. Early cultivation of sunflower in North America was primarily for livestock silage and seed for poultry. By the 1950s, improved Russian varieties with oil levels of 45–55% were available. Increased US production of these high-oil sunflower varieties spurred interest by oil crushers, which led to expanded US plantings, especially in the northern Great Plains (North Dakota and Minnesota). The discovery of cytoplasmic male sterility (CMS) by French scientists laid the foundation for the development of sunflower hybrids in the early 1970s. Hybrid sunflower, with higher yields and oil content and more uniformity, in comparison with open-pollinated varieties, provided the last great impetus in establishing sunflower was a worldwide crop (Figure 1).

Botany

Domesticated sunflower, *Helianthus annuus* L., is the same species as the wild, multiheaded, common annual sunflower found throughout the contiguous United States, northern Mexico, and southern Canada (Figure 2). The genus *Helianthus* is comprised of ~50 species within the tribe Helianthinae of the family Asteraceae. The only other *Helianthus* species grown commercially is the perennial *H. tuberosus*, commonly known as Jerusalem artichoke. There are 13 annual *Helianthus* species, all with $2n = 34$ chromosomes, and 37 perennial species, which may be diploid, tetraploid, or hexaploid. Many species freely hybridize with each other in nature, giving rise to intermediate forms, which has led to confusion in taxonomy. While *H. annuus* is a geographically diverse species occupying a wide range of habitats, other *Helianthus* species are very habitat specific and thus are endemic in a limited number of locations. For example, *H. niveus* ssp. *tephrodes* is only found in active sand dunes in southern California and in northern Sonora, Mexico. *Helianthus paradoxus* is only found in saline, marshy sites in western Texas and New Mexico, and *H. exilis* is only found in serpentine sites in northern California whose soils are nearly toxic to many nonadapted plants. Wild *Helianthus* species, both annual and perennial, have contributed many useful traits to domesticated sunflower, including disease resistance, drought and salt tolerance, and improved oil quality. All annual species, except *H. agrestis,* can be crossed with *H. annuus*. Of the perennial species, there has been more success in crossing tetraploid and hexaploid species with *H. annuus* than with the diploid perennial species.

Production Practices in North America

Sunflower production in the United States is concentrated in the northern Great Plains (North Dakota, South Dakota, Minnesota) with a secondary production area in the central Great Plains (western Kansas

and Nebraska, eastern Colorado) (Table 4), but there is some amount of sunflower grown in each of the 48 contiguous states (especially for birdseed). Most of the production recommendations have come from research conducted in North Dakota, but as interest in sunflower increases in other areas, new research generated from other states addresses these different environments.

Sunflower is traditionally planted between May 1 and the middle of June in the northern Great Plains, with hybrid maturities of 100–120 days to fit the short, 120-day average frost-free growing season of this region. Longer maturing hybrids are used where short growing seasons are not a restriction. Similarly, there are early maturing varieties that would be suitable for a double-crop situation. Double-cropped sunflowers are typically planted in July, either following the failure of an initial crop, or harvesting of a small grain crop. Yields of 2200–3500 kg ha^{-1} are attainable under optimal, irrigated conditions, while the average yield of sunflower in the US ranges from 1275 to 1515 kg ha^{-1}. The phenology of sunflower hybrid maturation is depicted in Table 5.

Sunflowers are typically planted when soil temperatures reach 10°C at the 10 cm depth. Below 10°C, germination is very slow. Sunflower is generally planted in row widths of 50–75 cm to match the available equipment, although solid seeding (widths <30 cm) is also practiced. Sunflower is planted 4–7 cm deep at rates of 37–62 000 seeds ha^{-1} for oilseed, and 35–50 000 seeds ha^{-1} for confection. Lower plant populations will produce larger head size and a greater proportion of large seed, which is desirable in confectionery sunflower. Conversely, high plant populations will result in smaller heads, which dry down faster, but also in thinner stalks which are more prone to lodging.

Sunflower has a root system characterized by both a deep taproot and an extensive fibrous root system, which makes it efficient at both water and nutrient uptake. While its water requirements are similar to that of corn, sunflower's greater efficiency can result in higher returns under moisture-limiting conditions. Sunflower responds well to nitrogen fertilization, with a general rule of 5 kg ha^{-1} nitrogen required for 100 kg seed ha^{-1}. Thus, for a yield target of 2000 kg seed ha^{-1}, the soil nitrogen content plus added nitrogen would be 100 kg ha^{-1}.

Early weed control is important in sunflower, and several preplant, pre-emergence herbicides are available for grass control, and to a lesser extent for broadleaf weed control. No post-emergence herbicides for broadleaf weed control are currently available. By 2004, hybrids developed through conventional breeding methods will be available with tolerance to both imidazilinone and sulfonylurea herbicides. There are no glyphosphate-resistant hybrids in any country, nor are there currently any other traits introduced into sunflower from other organisms beyond the genus *Helianthus* (i.e., sunflower is currently still a non-GMO crop).

Sunflower in the northern Great Plains typically flowers in August, ~60–70 days after planting. Four to five weeks postpollination are required for seed maturation, at which point, seed moisture is 30–40%. If the crop is killed by frost, seeds may be harvested without use of a chemical desiccant. Any conventional grain combine can be used to harvest sunflower, with a variety of attachments to facilitate catching the sunflower heads. Fields are

sometimes harvested with high moisture (i.e., 25%) seed to minimize losses due to birds and/or head rots. Seed moisture must be at 10% or less to retard fungal deterioration in storage, with 8% moisture preferable for storage over summer months.

Pest Problems

Cultivated sunflower has a number of pest problems, including diseases, insects, and birds. Since the genus *Helianthus* is indigenous to North America, there is a great diversity of insects and pathogens adapted to sunflower, plus a natural reservoir of these pests on wild *Helianthus*. In other continents, the diversity of sunflower pests and pathogens is generally less, although international seed movement has dispersed most sunflower pathogens around the globe.

Diseases

Sunflower is subject to a number of fungal, bacterial, and viral diseases, with fungi being the most numerous and economically serious. Diseases causing the most losses worldwide are *Sclerotinia* head and stalk rot, *Phomopsis* stem canker, rust, and downy mildew. Some diseases are serious in only a few countries, such as *Verticillium* wilt in Argentina or white rust (*Albugo*) in South Africa. Most sunflower diseases are caused by pathogens specific to sunflower, such as *Phomopsis helianthi*, *Alternaria helianthi*, and *Plasmopara halstedii*. Some of the most serious diseases, however, are caused by pathogens with wide host ranges, such as *Sclerotinia sclerotiorum*.

Disease organisms may be grouped based on plant parts affected. The only significant seedling disease is downy mildew (*Plasmopara halstedii*). Foliar diseases on sunflower include rust (*Puccinia helianthi*), blights caused by *Alternaria* (five species) and *Septoria helianthi*, powdery mildew (*Erysiphe cichoracearum*), bacterial blight (*Pseudomonas syringae* pv. *helianthi*), apical chlorosis (*P. syringae* pv. *tagetis*), sunflower mosaic virus, and sunflower chlorotic mottle virus. The main stem diseases of sunflower are *Sclerotinia* stalk rot (*S. sclerotiorum*), stalk rots caused by *S. minor* and *Sclerotium rolfsii*, Phomopsis stem canker (*P. helianthi*), charcoal rot (*Macrophomina phaseolina*), and bacterial stalk rot (*Erwinia carotovora*). Head rots are probably the most devastating because of their direct impact upon seed. The main pathogens responsible are *Sclerotinia sclerotiorum, Rhizopus (three species), Botrytis cinerea, and Erwinnia carotovora.*

Control of most diseases is accomplished primarily with resistant hybrids, and to a lesser extent with cultural practices. Single dominant genes are used to confer resistance to *Vertillium* wilt, and downy mildew. At least two dominant genes are required for resistance to *Phomopsis* stem canker, while resistance to Sclerotinia head rot and stalk rot is controlled polygenically, making it the most difficult disease to select resistance for. Very few diseases are managed with fungicides, primarily because of economics. Seed treatments for control of downy mildew have been very effective until the pathogen developed resistance to the fungicide metalaxyl. In some countries, foliar fungicides are used to manage *Phomopsis* and rust. The use of foliar fungicides is more practical with confection sunflower where the profit margin is greater than with oilseeds.

Insects

In the US, there is a wide variety of sunflower-specific, native insects that preferentially feed on either stems, leaves, roots, or seeds. Stem feeding insects on sunflower include at least four different cutworms (*Euxoa* species and *Agrotis orthogonia*), the sunflower stem weevil (*Cylindrocopturus adspersus*), the black sunflower stem weevil (*Apion occidentale*), the sunflower maggot (*Strauzia longpennis*), the longhorned sunflower stem girdler (*Dectes texanus*). Root feeding insects include the carrot beetle (*Ligyrus gibbosus*) and the sunflower root weevil (*Baris strenua*). Leaf feeding insects include grasshoppers (four *Melanoplus* species and *Camnula pellucida*), aphids (primarily *Aphis helianthi* and *Masonaphis masoni*), the painted lady caterpillar (*Vanessa cardui*), and the sunflower betel (*Zygogramma exclamationis*). Seed and head feeding insects include the sunflower moth (*Homeosoma electellum*), the sunflower midge (*Contarinia schulzi*), red sunflower seed weevil (*Smicronyx fulvus*), gray seed weevil (*Smircronyx sordidus*), banded sunflower moth (*Cochylis hospes*), sunflower head moth (*Gymnocarena diffusa*), sunflower seed maggot (*Neotephritis finalis*), and the sunflower headclipper weevil (*Haplorhynchites aeneus*). In other continents, insects are generally considered minimal or infrequent problems, and when they occur, they are generally caused by omnivorous insects such as aphids, plant bugs (*Lygus* spp.), and other nonsunflower-specific insects. Management of sunflower insect pests usually concentrates on cultural and chemical strategies. To date, no effective insect resistance has been used in cultivated sunflower.

Birds

Ranging from tiny sparrows (*Passeridae*) to large parrots (*Psittacidae*), birds are a constant problem to sunflower on all continents. In commercial birdseed

mixtures, sunflower is the preferred seed, so it is not surprising that the crop is beset by depredation by a wide variety of birds. In the US, the migratory red-winged blackbird (*Agelaius phoeniceus*) causes the most damage. In Europe, many different sparrows (*Passer* spp.) and doves (*Streptopelia* spp.) are the major problems, while in South America, parakeets (*Psitticidae*) and doves (*Columbidae*) predominate.

Seed losses due to bird feeding can easily exceed 10% in fields planted close to nesting areas, and losses of 100% are not unheard of. In the US, yield losses due to birds are significant enough to have necessitated the investigation of many different management strategies. There has been limited success in breeding for sunflower varieties that have physical barriers (long necks, tight bracts) to bird feeding. Most research efforts have explored cultural methods, habitat management, and mechanical frightening devices (noise makers). In the past, some growers have resorted to the use of avian poisons, now illegal, but even those efforts proved less than totally effective. One novel approach has resulted in a commercial product that contains the FDA-approved grape flavor component, which ironically many birds find repellant.

Sunflower Oil, Processing and Uses

Sunflower is grown worldwide, primarily as an edible oil crop. Sunflower oil is used mainly as a salad oil and frying oil, although it can be hydrogenated for use in margarines. In terms of world production, sunflower usually ranks fourth behind soybean, rapeseed or canola, and cottonseed. The oil content of oilseed sunflower varies from 40% to 50% by weight. There are currently two categories of sunflower oil: traditional and NuSun^{TM}. Traditional sunflower oil is characterized by a high concentration of linoleic acid and a moderate amount of oleic acid. Plant breeders, using conventional methods, have selected varieties in which oleic acid is the major fatty acid component, and this oil has been given the tradename of NuSun^{TM}. Oleic acid, a mono-unsaturated fatty acid, is considered by health and dietary experts to be better nutritionally than polyunsaturated fatty acids, like linoleic acid, and far superior than saturated fatty acids. While oleic acid levels of 80–90% are attainable, the frying industry prefers an oleic acid content of 55–60%, primarily because of the taste associated with the remnant linoleic acid. For a complete comparison of the fatty acid composition of various vegetable oils, see Table 1.

Oil extraction from sunflower seed is a relatively straightforward process. Seed is first thoroughly dried, de-hulled, and then flaked or rolled, and heated to 85–90°C. The crushed seed is then subjected to one of three extraction methods:

1. a mechanical screw press,
2. extraction with an organic solvent, usually hexane followed by distillation to remove the solvent, and
3. a combination of the screw press and solvent extraction.

In the US, the third method is the preferred method and generally recovers ~99% of the total seed oil. The crude oil is further processed to remove gums, waxes, free fatty acids, and odors. The refined oil is now suitable as a vegetable table oil, or can be hydrogenated and blended with soybean or canola oil for margarines.

Sunflower oil can be used as an alternative or additive to diesel fuel, and thus farmers could decrease their dependence upon petroleum fuels by substituting "farm-grown" fuel. For diesel engine use, sunflower oil requires more extensive purification including removal of waxes and gums. Minor engine modifications, including improved fuel filters, are also necessary to burn any vegetable oil. Since the energy content of sunflower oil is less than that of diesel, fuel consumption would be greater and power output less. As the price of diesel increases and the world supply diminishes, the feasibility of vegetable oil use in diesel engines becomes more of a reality.

Sunflower By-Products

Sunflower Meal

After sunflower seeds are crushed, the remaining meal is a high-protein product commonly used in livestock and poultry feeds. The meal contains 260–500 g kg^{-1} protein, 120–350 g kg^{-1} fiber (from remnant hulls), and 10–90 g kg^{-1} fat. Sunflower meal is lower in lysine content and higher in methionine than soybean meal and, thus, is usually combined with soybean meal in livestock feeds. Feeding trials with both dairy and beef cattle have adequately demonstrated the utility of sunflower meal.

Hulls

Sunflower hulls comprise 21–30% of the total seed weight and are often a wasted by-product. In oil extraction factories, the hulls are often burned as a source of heat, both for the plant and for the distillation process to remove the hexane solvent. Hulls, mixed with appropriate binders and glue, have also been molded into cylinders and sold as ersatz fireplace logs. Public buildings in the vicinity of processing plants have also used sunflower hulls for heating, with only minor modifications of their boilers.

A red dye, suitable as a FDA-approved food colorant, can be extracted from the hulls of purple-seeded sunflower. With the trend away from the use of synthetic dyes, many foods high in anthocyanin content have been viewed as dye sources. The anthocyanin content of purple-hulled seed ranges from 6 to $16\,g\,kg^{-1}$ of hulls, which compares favorably with that of other sources (grape skins, beet pulp). Natural red dyes lack the chemical stability of synthetic dyes, and thus may only be usable in certain applications.

Pectin, used in jellies and as a general food thickener, can be extracted from sunflower heads. The pectin content, after seed removal, is from 150 to $250\,g\,kg^{-1}$, and thus a hectare of sunflower could yield 200–350 kg pectin. Sunflower pectin is chemically a low-methoxyl pectin, as contrasted to high methoxyl pectins in apples and citrus. Low methoxyl pectins are used in making jellies low in sugar, and thus would be used primarily in diet food market.

Sunflower butter is a relatively new product intended to substitute for peanut butter in situations where peanut allergy is of concern. The product consists of ground, roasted sunflower seed mixed with sugar and other vegetable oils. It was introduced commercially in 2003 in the US.

Confection Sunflower

Sunflower varieties grown for human consumption are termed confectionery sunflower. The seeds generally roasted, salted, and eaten as a snack food, either "in-shell" or de-hulled to produce "nutmeats." The nutmeats are also used in breakfast cereals, "trail mixes," and in baked goods. Confectionery sunflower comprises 18–22% of US total sunflower production, with the US being the largest producer in the world market, followed by Argentina. Confectionery sunflower is characterized by its larger seed size and by having white or gray stripes on a black or brown background, as compared to uniform black color of oilseed sunflower.

Confectionery seed is graded on the basis of size. The largest seed, referred to as "in-shell," are those passing over a 7.9 mm round-hole screen, and generally make up 15–25% of the harvested seed. The medium-sized seed, destined for de-hulling for use as nutmeats, comprises 30–50% of the crop, and is that fraction recovered between a 7.9 and 7.1 mm round hole screen. The smallest seeds, passing through the 7.1 mm round hole screen, are used primarily as birdseed and comprise 15–20% of the crop.

Confectionery sunflower are genetically unique from oilseed sunflower, primarily because seed size and hull coloration are more important than oil content. As a group, they are much more susceptible to diseases and insects. Since the profit to the grower may be 25–100% greater than with oilseeds, extra management practices to control insects and diseases are more feasible.

Future Trends

Sunflower production in the US is in direct competition with soybean and rapeseed, which currently have the advantage of glyphosphate-resistance for weed management. Sunflower is also confronted by disease and insect problems that are of lesser concern in soybeans and rapeseed. The challenge to the sunflower industry is to make the crop as easy and profitable to grow as its competitors. The introduction of imidazilinone and sulfonylurea-resistant hybrids will offer growers a tool nearly as good as glyphospate resistance. Finding management schemes to control insects and diseases in sunflower will be the next challenge. Worldwide, *Sclerotinia* and *Phomopsis* are the two most devastating diseases. Both diseases can be managed with fungicides, but genetic resistance would be more economical and safer to the environment. While some seed companies are seeking *Sclerotinia*-tolerance via gene transfer from other crops, there are excellent sources of *Sclerotinia*-tolerance within the many *Helianthus* native to North America. Another option to make sunflower more competitive is to change its fatty acid composition to make the oil nutritionally better than other oils. A move in this direction is the introduction of Nusun™ hybrids, with oil nearly comparable with olive oil. As the world public becomes more health conscious, the benefits of NuSun™ oil should increase demand for sunflower oil and in turn generate more interest among growers. Commitments by large snack food processors and fast-food chain restaurants in the use of NuSun™ has been the first step in increasing domestic usage of sunflower oil.

T

TAXONOMIC CLASSIFICATION OF GRAIN SPECIES

L A Morrison, Oregon State University, Corvallis, OR, USA
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The common names of grain species often derive from localized, figurative expressions. They can lead to considerable confusion due to variations in region and language. In English, the problem is exacerbated by the adoption of common names from several languages, either as Anglicized words or direct translations. The grain legume *Cicer arietinum* offers a very good example. In languages of Europe and Asia, it is known as "cece" (Italian), "channa dhal" (Hindi), "garbanzo" (Spanish), "grão-de-bico" (Portuguese: beaked grain), "hummus" (Arabic), "Kichererbse" (German: "giggle peas"), and "pois chiche" (French: chickpea). In English, it is variously known as chickpea, gram, Bengal gram, chana, Egyptian pea, and garbanzo bean. Another problem is the changed usage of a common name from one region to another. In Europe, corn refers to cereal grains generally whereas in the Americas, it specifically refers to maize (*Zea mays*).

Taxonomy – A System of Names to Avoid Confusion

Common names can often have multiple or misleading associations. If not qualified, pigweed can collectively refer to members of the genus *Amaranthus* without distinguishing between the weedy versus grain amaranth forms. The "wheat" in buckwheat (*Fagopyrum esculentum*; Figure 1) and Inca wheat (*Amaranthus caudatus*: Figure 2) creates the false impression of a relationship with wheat (*Triticum* species: Figure 3), when in fact wheat and these two pseudocereal species are far apart from each other in evolutionary relationships, in biology, and in grain attributes. A more reliable means of communicating is provided by

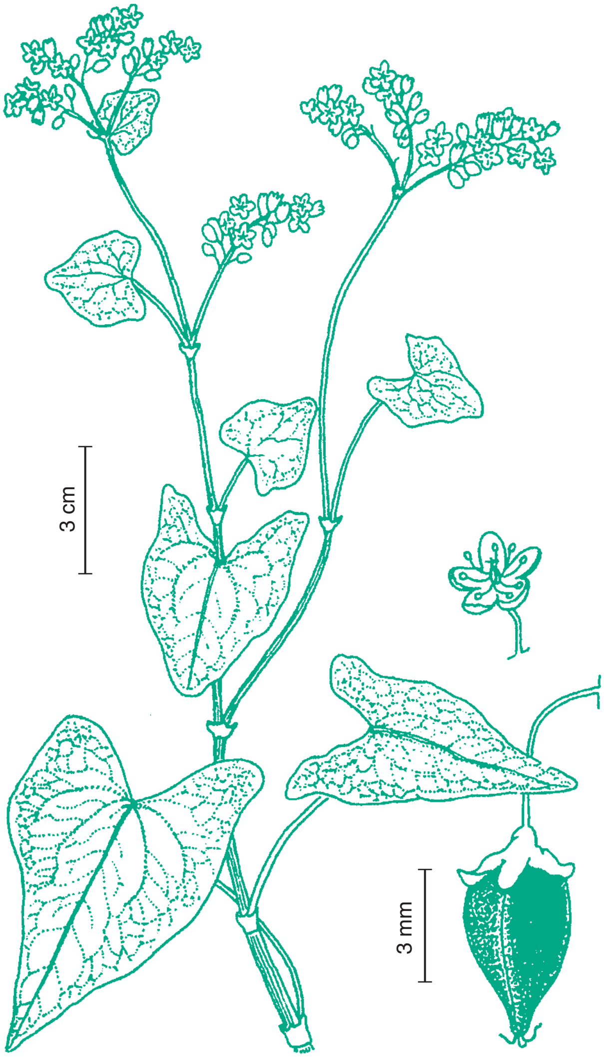

Figure 1 Buckwheat (*Fagopyrum esculentum*). Its dried, triangular-shaped fruit, a nut, resembles the beechnut produced by beech trees (*Fagus* spp.). This similarity is the source for the genus name *Fagopyrum*, which translates to "beechwheat." It also explains the derivation of the English common name buckwheat. "Buck-" is the Anglicized version of the German word for beech, "Buche." (Adapted from Williams JT (ed.) (1995) *Cereals and Pseudocereals*. London: Chapman and Hall.)

Figure 2 A mature specimen of *Amaranthus caudatus*, the most important of the Andean grain amaranths. It is still known by the ancient Incan name "kiwicha." Seeds (left) are ~1 mm in diameter and have a curved embryo. (Reproduced with permission from Vietmeyer ND (ed.) (1989) *Lost Crops of the Incas*. Washington, DC: National Academy Press.)

scientific names, which are assigned by a system known as taxonomy.

A taxonomic name consists of a genus and a species name which, when combined as a binomial, provide a unique identifier for the grain in question. This name is universally recognized in all scientific circles and removes the confusion created by common names, as the following example illustrates. *Amaranthus caudatus, A. creuntas*, and *A. hypochondriacus*, form the group known as grain amaranths, major food staples in the pre-Columbian Americas, which have now regained importance and promise as new pseudocereal grains in international agriculture (*see* **AMARANTH** and **PSEUDOCEREALS, OVERVIEW**). Their taxonomic names distinguish these grain amaranths from other weedy *Amaranthus* species variously known as pigweed, amaranth, or water hemp.

Although some common names have been accepted into international usage, they can still create problems within a scientific context. For example, in large species groups such as the wheats, scientific names make distinctions where common names cannot. The term wheat does not differentiate between the wild and domesticated species of *Triticum*, nor between the species of *Triticum* and its sister genus *Aegilops*. The common name farro can collectively refer to any one of three hulled wheat species – *T. monococcum*, a diploid wheat which is a minor crop species; *T. dicoccum*, a primitive tetraploid wheat also known as emmer; and *T. spelta* (= *T. aestivum* ssp. *spelta*), a hexaploid wheat known as spelt which is still grown in Europe and Asia and now a specialty wheat in the USA and Canada. Common wheat and bread wheat are equivalent names that can encompass a complex of hexaploid wheats when they are classified under one species name, *Triticum aestivum*, thereby including forms that are neither common nor necessarily amenable to breadmaking (Figure 3) (*see* **WHEAT**: Genetics).

Taxonomy – A System of Relationships

Inherent in taxonomic groupings is an indication of evolutionary relationships. Thus, the taxonomy of grain species has some bearing on plant morphology, grain composition, and function, and many other attributes important to grain science. Unfortunately, taxonomy is not an exact science and is subject to conceptual disagreements and opposing interpretations. Currently, the debate primarily centers on taxonomy's ability to accurately represent phylogeny – the branching ancestor/descendent relationships that connect all plant species. On one side, are molecular systematists, who argue that classifications must reflect evolutionary relationships. On the other side, are traditionalists, who counter that the reliable order and structure of taxonomy is more important than an exact representation of phylogeny. Supporting the traditional view is the fact that phylogenetic classifications are continually subject to change due to the evolving interpretations of new evidence. Another key element of the argument is how to construct a better naming system than the one currently in use. Grain researchers will encounter the effects of

Figure 3 Variations in the appearance of heads of wheat species, one of many morphological characteristics used for their taxonomic classification. From left to right, the wheat species are (including their genome assignments and common names): *T. boeoticum* (2x: wild einkorn), *T. monococcum* (2x: einkorn), *T. dicoccoides* (4x: wild emmer), *T. dicoccum* (4x: emmer), *T. durum* (4x: macaroni wheat), *T. carthlicum* (4x: Persian wheat), *T. turgidum* (4x: rivet wheat), *T. polonicum* (4x: Polish wheat), *T. timopheevii* (4x: Timopheev's wheat), *T. aestivum* (6x: bread wheat), *T. sphaerococcum* (6x: shot wheat, Indian dwarf wheat), *T. compactum* (6x: club wheat), *T. spelta* (6x: spelt wheat), and *T. macha* (6x: macha wheat). The diploid A-genome species, *T. urartu*, is not shown here. 2x = diploid; 4x = tetraploid; 6x = hexaploid. these conflicting views in different taxonomic nomenclature and classification schemes for the same grain species or species groups. While the debate rages, the taxonomic system developed in the eighteenth century by the Swedish scientist Carolus Linnaeus is still intact, flexible enough to have grown with the advances of modern genetics and evolutionary studies.

Taxonomy – What It Is and How It Started

Taxonomy is a much-misunderstood discipline that is often cast as an outdated exercise. It provides a system by which plants are classified, named, and identified. Classification consists of the circumscription, grouping, and hierarchical ranking of a plant entity (taxon) or entities (taxa). Naming, or nomenclature, is governed by a set of rules laid out in the International Code of Botanical Nomenclature (ICBN) and in the more specialized rules for domesticated plants, the International Code of Nomenclature for Cultivated Plants (ICNCP). Identification, which usually goes hand-in-hand with nomenclature, is a determination based on similarity of a taxon's membership in an existing group or a new group.

Linnaeus initiated modern taxonomy with the publication of "Species Plantarum" in 1753, which classified every plant then known to him. The Linnaean system was not an isolated endeavor, but it was built on a long history of scientific attempts, beginning with the Greek Theophrastus (third century BC) and the Roman Pliny the Elder (first century AD), to construct universal naming and classification systems. The Linnaean binomial system, consisting of genus and species names, resolved the problem of concisely and uniquely naming a plant. Continuing with the scientific heritage that preceded him, Linnaeus used Latin as the language of taxonomic names and descriptions. In his time, Latin was the universal language by which European scholars could communicate. Linnaeus took classical Latin and created a new botanical form with a specialized terminology for plant structures and the flexibility for adopting Latinized words taken from other languages. Modern attempts to replace botanical Latin with English for taxonomic descriptions have so far been unsuccessful, leaving this particular Linnaean heritage intact.

Origins of Taxonomic Names

Many Linnaean names for agricultural plants have their roots in the vernacular of the ancient Greeks and Romans. For example, the genus names for grains were derived from names that often related to a particular function, activity, or trait. In other cases, common names developed out of an association with a family or person. Thus, *Triticum* comes from the Latin "tero" meaning "I thresh"; "Cicer," which translates to chickpea, has its origin in the Greek "kiros," referring to the Roman family "Cicero;" *cereale* is taken from "Ceres" the Roman goddess of agriculture in a broad sense and of cereal grain in a more narrow one. In the original Linnaean system, species names usually conveyed information about a trait so that when combined with the genus name, they produced an identifying designation for the taxa in question as these examples illustrate. *Amaranthus caudatus* translates as the "amaranth ending with a tail-like appendage," a reference to this species' long, tail-like inflorescence (Figure 2); *Cicer arietinum* as "chickpea shaped like a ram's head," a reference to the kabuli type of chickpea; *Fagopyrum esculentum* as "edible buckwheat" (Figure 1); *Triticum monococcum* as "one-grained wheat" (Figure 3); *Secale cereale* as "cereal rye."

For species named by Linneaus, the intertwining of scientific names with the original vernacular helps to explain their respective derivations. The origin of the term common wheat hails back to an older, no longer accepted, species name *T. vulgare*, which translates as "common wheat." The use and derivation of corn and the genus name, *Zea*, provide another example. In Europe, corn refers generally to cereal grains, or the seed itself, whereas in the Americas, it specifically denotes the species *Zea mays*. The English word corn has its roots in the German word for grain, "korn." The Greek word "zea," like corn, referred to grain in a general sense. Linnaeus selected *Zea* as a genus name for the new cereal-grain species that had arrived in Europe following the discovery of America and for which there was no European vernacular name upon which to draw. As a consequence, the English common name corn was adopted into the American English vernacular to refer to the only major New World cereal grain known in the eighteenth century.

The Use of Genus and Species Names

Tables 1 and 2 list common and scientific names for grain species. The usual convention is to write both genus and species names in italics, with the genus name having a capital as the first letter, followed by the species name (known as the specific epithet) all in lower case. When a grain consists of a group of species, the plural abbreviation "spp." is used. In text, the genus name component of the binomial is spelled out the first time and abbreviated to its first letter, except when beginning a sentence, for each following use as was done above with *Amaranthus* and *Triticum*.

Table 1 Classification of the grass family, Poaceae (Gramineae), all monocotyledonous plants: cereal grain species and their common names[a]

Subfamily	*Tribe*	*Genus and species*	*Common name*
Bambusoideae (Ehrhartoideae)[b]	Oryzeae	*Oryza glaberrima*	African rice
		Oryza sativa	Rice
		Zizania aquatica	Wild rice
		Zizania palustris	Northern wild rice
Chloroidoideae	Eragrostideae	*Eleusine coracana*	Finger millet, African millet, Indian millet
		Eragrostis tef	Tef, teff, teff grass
Panicoideae	Andropogoneae	*Sorghum bicolor*	Sorghum, grain sorghum, great millet, Kaffir-corn, durra, milo
		Zea mays	Corn, maize
		Coix lacryma-jobi	Coix, Job's tears, Adlay millet
	Paniceae	*Digitaria exilis*	Fonio, fonio millet, hungry-rice
		Echinochloa esculenta	Japanese barnyard millet, Japanese millet, Siberian, or marsh millet
		Panicum miliaceum	Common millet, broom millet, broomcorn millet, proso millet
		Panicum sumatrense	Blue panic, little millet, sama
		Paspalum scrobiculatum	Kodo millet
		Pennisetum glaucum	Pearl millet, cattail millet
		Setaria italica	Foxtail millet, Italian millet
Pooideae	Agrostideae (Poideae)[b]	*Phalaris aquatica*	Phalaris, Harding grass, towoomba Canary grass
	Aveneae (Poideae)[b]	*Avena sativa*	Oat, side oat
		Avena abyssinnica	Abyssinian oat
	Triticeae	*Hordeum vulgare*	Barley
		Secale cereale	Rye, cereal rye
		× *Triticosecale* sp.[c]	Triticale
		Triticum aestivum	Wheat, common wheat, bread wheat
		Triticum dicoccum	Emmer, farro
		Triticum durum	Durum wheat, hard wheat, macaroni wheat
		Triticum monococcum	Einkorn, small spelt, farro
		Triticum spelta	Spelt, spelt wheat, hulled wheat, dinkel wheat, farro
		Triticum turgidum	Rivet wheat, cone wheat

[a] Following the classification system outlined in Heywood VH (1993) *Flowering Plants of the World*. Oxford, UK: Oxford University Press.
[b] Alternative subfamily and tribal classification assignment according to the Grass Phylogeny Working Group (GPWG).
[c] Triticale is an intergeneric hybrid that was created by a cross between wheat and cereal rye. The × preceding its genus name, which combines *Triticum* and *Secale*, indicates its hybrid origin. The "sp." (one species) is required because no species name has been assigned.

In cases where two genera with the same first letter are discussed together, then the second letter of the species name is included in the abbreviation, e.g., in discussions of the millets, *Pa*. for *Panicum* and *Pe*. for *Pennisetum*. Authority names (usually abbreviated, and not in italics) are not included in Tables 1 and 2 as they are not essential for the completeness of the binomial. However, it is useful in research articles and literature reports to include the authority citation at the first mention of the species as a way of clarifying which taxonomic concept is being followed.

The authority refers to the botanist or researcher who named the species, e.g., "L." for Linnaeus in *T. monococcum* L.; "Desf." for R L Desfontaines in *T. durum* Desf. Authorities are important for synonymy, the component of taxonomy that deals with the historical naming of a species. When the name and classification of a grain species is in question due to competing treatments, synonymy provides a way to trace its taxonomic handling and to determine which is the correct and legitimate name according to the ICBN. In dealing with synonymy, knowing the authority is critical.

Taxonomy – Rank and Hierarchy

In classification, taxonomy provides a system for grouping species into ranked hierarchies. All grain species are flowering plants and thus are classified together in the class Angiospermae. Members of this class reproduce sexually with the male and female organs located in flowers, which can be showy (pseudocereals and pulses) or inconspicuous (cereals). Their seeds are protected by a fruit, which can be fleshy or dried. In the case of cereals, the fruit is reduced to a thin outer tissue that is adherent to the seed. In botanical

Table 2 Dicotyledonous grain and oilseed species and their common names[a]

Family	*Tribe*	*Genus and species*	*Common name*
Amaranthaceae	Amaranthoideae	*Amaranthus caudatus*	Amaranth, grain amaranth, Inca-wheat
		Amaranthus cruentas	Purple amaranth, red amaranth
		Amaranthus hypochondriacus	Prince's feather
Asteraceae (Compositae)	Cardueae	*Carthamus tinctorius*	Safflower
	Heliantheae	*Guizotia abysinnica*	Niger, niger seed
		Helianthus annus	Sunflower
Brassicaceae (Cruciferae)	Brassiceae	*Brassica napus*	Canola, oilseed rape, rape
		Brassica spp.	Mustard
		Crambe abysinnica	Crambe
Chenopodiaceae	Cyclobeae	*Chenopodium quinoa*	Quinoa
Fabaceae (Leguminosae)	Aeschynomeneae	*Arachis hypogaea*	Peanut, groundnut, gooper
	Cicereae	*Cicer arietinum*	Chickpea, garbanzo bean, gram
	Genisteae	*Lupinus albus*	White lupin
		Lupinus angustifolius	Blue lupin
	Phaseoleae	*Glycine max*	Soybean
		Phaseolus lunatus	Lima bean, butter bean
		Phaseolus vulgaris	Bean, kidney bean, pinto bean, navy bean, cannellini bean
		Vigna angularis	Adzuki-bean
		Vigna radiata	Mung bean, golden gram, green gram
		Vigna unguiculata	Black-eyed pea, cowpea
	Vicieae	*Lathyrus sativus*	Chickling pea, chickling vetch
		Lens esculentus	Lentil
		Pisum sativa	Garden pea, field pea
		Vicia faba	Faba bean, broad bean
Linaceae		*Linum usitatissimum*	Linseed, flax
Malvaceae	Hibisceae	*Gossypium* spp.	Cottonseed
Pedilaceae		*Sesamum indicum*	Sesame, sesame seed
Polygonaceae		*Fagopyrum esculentum*	Buckwheat, Japanese buckwheat, silverhull buckwheat

[a] Following the classification system outlined in Heywood VH (1993) *Flowering Plants of the World*. Oxford, UK: Oxford University Press.

terminology, this unusual fruiting structure of the cereals is called a caryopsis.

The most useful grouping at this level of the hierarchical ranking system divides grain species into two evolutionary lines known as the monocots (subclass Monocotyledoneae) and dicots (subclass Dicotyledoneae) (Table 3). Monocot and dicot refer to the presence of one or two embryonic leaves (cotyledons) in the seed and young seedling. Other easily identifiable morphological traits that differentiate between members of these two subclasses include flower parts in threes, parallel-veined leaves, scattered vascular bundles, and fibrous adventitious root system for monocots; flower parts in fours or fives, net-veined leaves, vascular bundles located in a ring, and a primary tap root for dicots. It is noteworthy that botanists often disagree on the higher rank categories (e.g., division Anthophyta versus class Angiospermae; class Monocotyledones versus subclass Monocotyledoneae) and particularly on classification at the order level. Thus, Tables 1–3 reflect one of several possible higher-order classifications.

The taxonomic rank family is the most useful of the higher ranks. Family names end in "–aceae" except for several older names that were in use before the ICBN standardized the suffix spelling. Thus, in grain taxonomy, two family names are occasionally encountered – Gramineae (old) and Poaceae (new); Leguminosae (old) and Fabaceae (new); Cruciferae (old) and Brassicaceae (new); Compositae (old) and Asteraceae (new). The other useful higher taxonomic ranking is tribe, a subdivision of family, which is identified by an "–eae" ending. All the cereal grains (e.g., maize, rice, sorghum, wheat) are monocots and belong to the grass family, Poaceae. On the other hand, the group of dicot grains and oil seeds comprises a diverse mixture of families. The pulses or grain legumes (e.g., beans, peas, soybeans), which are the largest group of dicot grains, are classified in the family, Fabaceae. Other families include one or just a few dicot grain or oil species, e.g., Amaranthaceae (grain amaranths), Polygonaceae (buckwheat), Asteraceae (safflower and sunflower), Malvaceae (cottonseed), and Brassicaceae (canola). Subdivisions of these families into subfamilies and/or tribes are reflections on the size of the family and the necessity for subgroupings within it.

Grain species can be subdivided into infraspecific categories known as subspecies (ssp.), variety (var.),

Table 3 Hierarchical classification[a] from subclass to genus for grain and oilseed species with their use-category assignments

Subclass and superorder	*Order*	*Family*	*Subfamily*	*Tribe*	*Genus*	*Use category*
Monocotyledoneae						
Commelinidae	Poales	Poaceae	Bambusoideae (Ehrhartoideae)[b]	Oryzeae	*Oryza*	Cereal
					Zizania	Cereal
			Chloridoideae	Eragrostideae	*Eleusine*	Cereal
					Eragrostis	Cereal
			Panicoideae	Andropogoneae	*Coix*	Cereal
					Sorghum	Cereal
					Zea	Cereal
				Paniceae	*Digitaria*	Cereal
					Echinochloa	Cereal
					Panicum	Cereal
					Paspalum	Cereal
					Pennisetum	Cereal
					Setaria	Cereal
			Pooideae	Agrostideae (Poeae)[b]	*Phalaris*	Cereal
				Aveneae (Poeae)[b]	*Avena*	Cereal
				Triticeae	*Hordeum*	Cereal
					Secale	Cereal
					× *Triticosecale*	Cereal
					Triticum	Cereal
Dicotyledoneae						
Asteridae	Asterales	Asteraceae	Lactucoideae	Cardueae	*Carthamus*	Oil seed
			Asteroideae	Heliantheae	*Guizotia*	Oil seed
					Helianthus	Oil seed
	Scrophulariales	Pedaliceae			*Sesamum*	Oil seed
Caryphyllidae	Caryophyllales	Amaranthaceae	Amaranthoideae		*Amaranthus*	Pseudocereal
		Chenopodiaceae		Cyclobeae	*Chenopodium*	Pseudocereal
	Polygonales	Polygonaceae			*Fagopyrum*	Pseudocereal
Dilleniidae	Malvales	Malvaceae			*Gossypium*	Oil seed
Rosidae	Fabales	Fabaceae	Papilionoideae	Aeschynomeneae	*Arachis*	Pulse, oil seed
				Cicereae	*Cicer*	Pulse
				Genisteae	*Lupinus*	Pulse
				Phaseoleae	*Glycine*	Pulse, oil seed
					Phaseolus	Pulse
					Vigna	Pulse
					Linum	Oil seed
				Vicieae	*Lathyrus*	Pulse
					Lens	Pulse
					Pisum	Pulse
					Vicia	Pulse
	Geraniales	Brassicaceae		Brassiceae	*Brassica*	Oil seed
					Crambe	Oil seed
		Linaceae			*Linum*	Oil seed

[b] Alternative subfamily and tribal classification assignment following the Grass Phylogeny Working Group (GPWG) revision.

and forma (f.). Because there is no clear agreement on subspecies and variety, the two are often used interchangeably, although it is possible to treat variety as a subrank to subspecies. When the subspecies (or variety) is the taxonomic type that defines a particular species, then the ICBN requires that this subspecies (or variety) repeats the species name – e.g., *T. aestivum* ssp. *aestivum*. In general discussions, it is not necessary to include the repetitious infraspecific form. Thus, in this example, it is sufficient to cite the species name *T. aestivum* when referring to bread wheat. Forma is the smallest category and is infrequently encountered.

The infraspecific ranks are intended to describe variants that form distinct groups defined by genetics, morphology, ecology, and distribution. How a particular taxonomist chooses to classify infraspecific variation often appears arbitrary. For example, a recent taxonomic treatment of the wheats uses variety for the wild wheat genus *Aegilops*

(e.g., *A. speltoides* var. *ligustica*) but subspecies for the domesticated genus *Triticum* (e.g., *T. turgidum* ssp. *durum*). Here, the infraspecific ranks should be viewed as approximately equivalent. This example also illustrates the difficulty in reflecting evolutionary relationships within the framework of taxonomic classification. The infraspecific variation in domesticated *Triticum* species is the product of human selection pressure, which is arguably on a different evolutionary scale than the variation in the wild species of *Aegilops*. Therefore, the taxonomist's choice of variety for *Aegilops* and subspecies for *Triticum* should not be construed as a necessarily accurate representation of evolutionary status.

Taxonomic Disagreements

With taxonomic classification, there is not necessarily a right or a wrong treatment of a group. Taxonomists and the researchers working with a particular group often disagree. As a consequence, different names for the same species can be found in use. For those who are not schooled in the synonymy of the group in question or unaware of the details of the controversy, conflicting taxonomic treatments are confusing. In the case of grain species, taxonomic debates usually deal with both the status of cultivated taxa (usually species status) and the relative importance of genetic evidence in defining species concepts. There is no clear separation of these two points, partly due to the historical tradition on which taxonomy has been built and the inconsistencies in how domesticated plants are viewed within an evolutionary context. The opposing species concepts evident in the handling of the wheats throughout the encyclopedia offer an excellent example of the dilemmas found within a taxonomic debate. Morphological diversity in the tetraploid and hexaploid wheats illustrates the potential for variation that developed under the direction of humans acting as evolutionary selection agents. This variation originally correlated with eco-geographical distributions and if allowed to continue in isolation over geologic time would have possibly led to new species. Wheat geneticists stress the need to portray accurate genetic relationships, circumscribing wheat species on the basis of their close genetic similarities. Thus, in the AB-, ABD-genome groups, geneticists accept only two species, each with several infraspecific forms – *T. turgidum* and *T. aestivum*. On the other side of the fence, are those who stress the importance of recognizing the variation of domesticated forms by naming many tetraploid and hexaploid wheat species (Table 1). Provided that the rules of nomenclature are followed, differing treatment concepts are acceptable. On this basis, *T. spelta* and *T. aestivum* ssp. *spelta* are both correct as are *T. durum* and *T. turgidum* ssp. *durum*, respectively describing the same wheats, albeit from different taxonomic perspectives.

Cultivated Plant Taxonomy

Another difficulty in infraspecific taxonomy is the confusion over variety and cultivar. In the realm of cultivated plant taxonomy, variety and cultivar have been used as equivalent terms. As in the case of subspecies and variety, there is no consensus. However, it is important to make the distinction between the botanical use of variety (*varietas*) as an infraspecific rank and the horticultural (i.e., domesticated plant) use of variety to describe a domesticated plant variant. Unfortunately, the ICNCP lends some confusion to this issue because it treats variety and cultivar as synonymous but with the qualification that a botanical variety is a taxonomic entity whereas a cultivated plant variety is not.

A domesticated variety or cultivar has a fancy name not a Latinized botanical name that is italicized. At their first mention, cultivar names are enclosed by single quotation marks. When mentioned alone without their Latin binomial, they can be preceded by cultivar or its abbreviation "cv." A good rule of thumb is to use variety within the botanical context as a term that is interchangeable with subspecies and to reserve cultivar for describing a named domesticated variant. The derivation of cultivar should help to maintain this distinction because it is formed from "cultivated variety" by combining the first five and three letters respectively. Several examples should help to clarify this usage – *Zea mays* "Bronze Beauty" or maize cultivar "Bronze Beauty"; *Lens culinaris* "Laird"; *Avena sativum* "Wallaroo" *Arachis hypogaea* ssp. *fastigiata* "Georgia Red"; *Amaranthus cruentus* "K343"; *Cicer arietinum* "Kranthi."

The term landrace is often encountered in discussions of crop germplasm. It refers to an indigenous grain species within a local farming system. Landraces predate modern agriculture and often are ancient forms that may have been in cultivation for hundreds or thousands of years. Landraces are usually composed of a mixed population of several forms that vary by agronomic traits such as disease resistance, maturity, yield, and cold tolerance. The mixture also may include different species or morphological forms. For example, wheat landraces collected during the late 1940s in southeastern Turkey can be composed of 10 or more different types of *T. aestivum* (= *T. aestivum* ssp. *aestivum*) and *T. durum* (= *T. turgidum* ssp. *durum*). The advantage of landraces in subsistence farming systems is the guarantee of a crop under all types of growing conditions. Thus, if the farmer faces a particularly bad disease year, the

resistant types of the landrace will survive and yield a harvestable grain. Unfortunately, a clear-cut distinction between landrace and cultivar is not always maintained. It is not uncommon for a landrace to be identified as a cultivar by one genebank and as a landrace by another. The vernacular names for landraces do not have taxonomic standing.

Taxonomy – In Use

As a standardized system for classification of plants, taxonomy provides a useful way for tracing the origins of grain species. By knowing the names of wild progenitors and related domesticated species, researchers can make informed decisions when selecting material for study or for breeding programs. Likewise, knowing the taxonomic characters by which species are classified enables researchers to verify the identity of research material. It is possible for genebank and research collections to hold and distribute mislabeled or misidentified wild and domesticated germplasm.

The wheats offer a practical example of the importance of taxonomy in the selection and use of research material. Because there are several conflicting taxonomic concepts for the wild and domesticated wheats, a seed request may not be filled with the species actually requested. A general, unspecified request for accessions of the diploid A-genome progenitor of tetraploid and hexaploid wheat species may be incorrectly filled with either *T. boeoticum* or *T. monococcum*. While the wild *T. boeoticum* and domesticated *T. monococcum* both have a form of the A-genome, neither was involved in the evolution of *T. durum* (AB genomes) and *T. aestivum* (ABD genomes) (Figure 3). The correct species for this request would be *T. urartu*. Since *T. urartu* and *T. boeoticum* are morphologically very similar to each other, a researcher, who is unfamiliar with the taxonomic characters that differentiate them, may erroneously mistake *T. boeoticum* for *T. urartu*.

Taxonomy and Allergies

Taxonomic relationships have a practical application for identifying potential allergic cross-reactions. For example, a person with a proven allergic reaction to wheat grain would be more likely to have similar problems with rye but less with the more distantly related cereal grain species such as rice or maize (Table 1). This consideration is particularly relevant to celiac disease (*see* **CELIAC DISEASE**), for which the prime cause is the gluten proteins found in wheat. Celiacs are also warned to avoid eating the grain of barley, rye, and triticale, closely related species in the tribe Triticeae. Although oats, which are classified in tribe Aveneae, are considered to be less harmful for celiacs, some such individuals find that they must avoid them. On the other hand, celiacs may eat foods based on other cereal grains, which are classified in more distantly related tribes (e.g., maize, millet, rice, sorghum) as well as any of the dicot grains. Within the context of taxonomy, the possible cross-reaction with oats but not with maize, millet, rice, and sorghum is understandable. The tribes Triticeae and Aveneae are located in the same subfamily, the Pooideae. On the other hand, maize, millet, and sorghum are classified in the subfamily Panicoideae and rice in the subfamily Bambusoideae.

Attempts at prediction of allergic cross-reaction may not be valid if making comparisons with respect to different anatomical parts of the plant and different routes into the body – for example, the inhalation of pollen versus the ingestion of grain. It may thus be possible for a person, who is allergic to wheat pollen, to suffer no adverse reactions to the wheat grain. However, there is at least anecdotal evidence that individuals, who experience mild ingestion intolerance to cereal grains, may have these symptoms exacerbated in pollen season. Also, allergic cross-reactions are observed between pollens of different species, implying that sensitization by one species can confer allergy to others. Thus, a positive test reaction to pollen from one species does not necessarily mean that it is the one causing clinical symptoms, nor need it have been the one responsible for the original sensitization. The real culprit may be another, cross-reacting pollen. Here, taxonomy offers a practical tool for elucidating such situations. For the monocot grains, only the grass family Poaceae is necessary to consider. Within the very diverse group of dicot grains, pseudocereals, and oil seeds, the higher taxonomic rankings of Super Order and Order are of practical use for evaluating allergic cross-reactions. In providing only a brief introduction into the taxonomy of grain species, Table 3 illustrates the hierarchical relationships that should be considered in dealing with potential cross-reactions.

Future Trends in Taxonomy

As is evident in the above discussion, taxonomy is not an exact science but is subject to conflicting, and often changing, interpretations. When taxonomic disagreements prevail, the focus shifts away from taxonomy's real value for aiding communication among scientists. In the case of the wheats, a 50-year-old controversy over how to classify wild and domesticated taxa by evolutionary relationships has created a confusing situation with many different classifications and no consensus for names or species concepts. This controversy illustrates the possible problems that

lie ahead should the current trend continue among many leading molecular systematists to restructure traditional taxonomy into a "natural" system that accurately displays phylogenetic relationships (cf., Grass Phylogeny Working Group website below). Because concepts of plant phylogeny are changing rapidly with the sophisticated tools of molecular biology, an attempt to structure taxonomy around evolutionary concepts may lead to a situation of constant taxonomic flux. Traditionalists argue that taxonomy should continue as it now stands guided by the ICBN. Molecular systematists suggest other naming systems and other ways of classifying, which could lead to a re-invention of taxonomy. Suggestions for two systems have been proposed. In this scenario, the traditional Linnaean system would remain intact and another separate system, which would be designed to accommodate to changing concepts, would be developed for phylogenetic reconstruction.

J R N Taylor, University of Pretoria, Pretoria, South Africa

Introduction

Teff [*Eragrostis tef* (Zucc.) Trotter], commonly known as "tef," is a tropical cereal. Teff cultivation and consumption as human food is mostly confined to Ethiopia. This article highlights the origin, cultivation of the teff plant, production, and storage of teff grain. Teff grain structure, anatomy, chemical composition, and physico-chemical properties of the major chemical components are assessed and described. Teff milling, processing of *injera* (the staple food of the majority of Ethiopians, a fermented, pancake-like, soft, spongy, sour, circular flatbread), and other food products made from teff are described. Finally, its potential, grain production limitations, and recommendations for future research to improve the teff crop and its grain utilization are enumerated.

Teff Crop Description and Cultivation

Description

Teff is a C_4 self-pollinated tetraploid cereal plant with a chromosome number of $2n = 4x = 40$. Teff is also an allotetraploid plant. The teff plant and panicles of some varieties are shown in Figure 1. Teff's root system is fibrous and most stems are erect, while others are bending or elbowing types. It has a panicle type of inflorescence showing different forms, from loose to compact. Its spikelets have 2–12 florets. Each floret has a lemma, palea, three stamens, mostly two ovaries (in some exceptional cases three), and feathery stigmas. In most varieties, the plant height is 50–120 cm. A single teff plant can produce up to 50 000 grains.

Name and Origin

Teff [*Eragrostis tef* (Zucc.) Trotter] belongs to the family of Poaceae, subfamily Eragrostoidae, tribe Eragrosteae, and genus *Eragrostis*. About 300 species are known in the genus *Eragrostis*, of which teff is the only cultivated species. Chloridoideae is used synonymously for Eragrostoidae of teff. Vernacular names in different parts of the world are as follows:

- *Tahf*: Arabic,
- *Tef*, *teff*, Williams lovegrass: English,
- *Xaafi, tafi, taafi*: Oromo (O)/Afar/Sodo, *tafe-e*: Had, *t'ef*, *teff*, *taf*: Amarinya (A), Tigrinya (T): Ethiopian languages,
- *Mil èthiopien*: French, and
- *Chimanganga, ndzungula (Ch), chidzanjala (Lo)*: Malawi.

Teff is indigenous to Ethiopia. Ethiopia is also considered the leading world center for teff genetic diversity. Records indicate that by 1997, the Ethiopian Biodiversity Institute had conserved some 3842 accessions of teff for varietal improvement study and to reduce genetic erosions. The exact details on teff domestication are unclear. However, teff is believed to have been first domesticated by the pre-Semitic inhabitants of Ethiopia and is assumed to have originated in northeastern Africa.

Even though teff is an allotetraploid plant, to date, its diploid putative ancestors are not exactly established. But, based on the morphological data and cytological evidence, the following species have been suggested as the ancestors and contributors to teff origin:

- *Eragrostis. aethiopica, E. atrovirens, E. longifolia, E. macilenta, E. pilosa*, and *E. psedudo tef* as ancestor species of teff.
- *E. aethiopica, E. bicolor, E. cilianensis, E. curvula, E. pilosa*, and *E. mexicana as* contributor species to the origin of teff.
- *E. aethiopica, E. barrelieri, E. bicolor, E. cilianensis, E. heteromera, E. mexicana, E. minor, E. papposa*, and *E. pilosa* as very closely related species to teff.
- *E. aethiopica* 2x, *E. barrelieri* 6x, *E. cilianensis* 2x, 4x, 6x, *E. mexicana* 6x, *E. minor* 2x, 4x, and *E. pilosa* 2x based on cytological evidence as closely related species to teff.

An attempted interspecific cross between teff and some wild *Eragrostis* species (*E. curvula*, *E. cilianensis* (4x), *E. pilosa* (4x), and *E. minor*) was not successful. However, it was recently reported that *E. tef* and *E. pilosa* can be crossed with fertile offspring, suggesting that *E. pilosa* or an ancestor closely related to *E. pilosa* is the most probable putative ancestor of teff.

Cultivation and Production

Teff is one of the major cereals in Ethiopia, comprising ~20% of cereal production. The annual production in Ethiopia is estimated to be $\sim 2 \times 10^6$ t. In Idaho, USA some teff grain is produced for the health-food market

and for *injera* making. In South Africa, teff is widely grown as a fodder crop during the summer-rainfall season. However, the production of a combination of grain and fodder varieties has been introduced only recently. In Australia, India, and Kenya, it is cultivated as a forage crop. Teff can adapt to a wide range of environments, i.e., moisture stress, high rainfall, different soil types, and a wide range of altitudes from near sea level to over 3000 m. However, the best conditions are 1800–2100 m above sea level, a temperature range of 10–27°C during the cultivation period, an annual rainfall of 750–850 mm, and rainfall of 450–550 mm during the growing season.

Teff is known to have fewer disease and pest problems in the field as compared to maize, sorghum, wheat, and barley. However, the productivity is low. The average national yield in Ethiopia is 9.4 quintal per hectare (q ha^{-1}). Lack of high-yielding cultivars, lodging, weeds, waterlogging, low moisture, and low-fertility conditions are major factors that contribute to the low grain yield. Threshing its tiny seed is also not an easy task. The yields of improved varieties using enhanced technologies (fertilizer, weed control, appropriate harvesting, and grain threshing) are in the range of 17–22 q ha^{-1}, and in some farms, under research conditions, the yield is as high as 27 q ha^{-1}.

Harvesting and Storage

Teff grain is harvested when the vegetative and reproductive parts (pedicel, lemma, palea, and glumes) turn yellow or straw color (45–60 days for very early maturing, 60–120 days for early maturing, and 120–160 days for late maturing). If harvested late, the grain loss will be significant due to shattering and the natural grain color can also fade. However, if the grain is harvested early, it may become vitreous or translucent. In Ethiopia, traditional harvesting is done manually using a sickle. The harvested panicles are gathered in batches, either on the day of harvestation or after ~1–3 days, and temporarily stacked

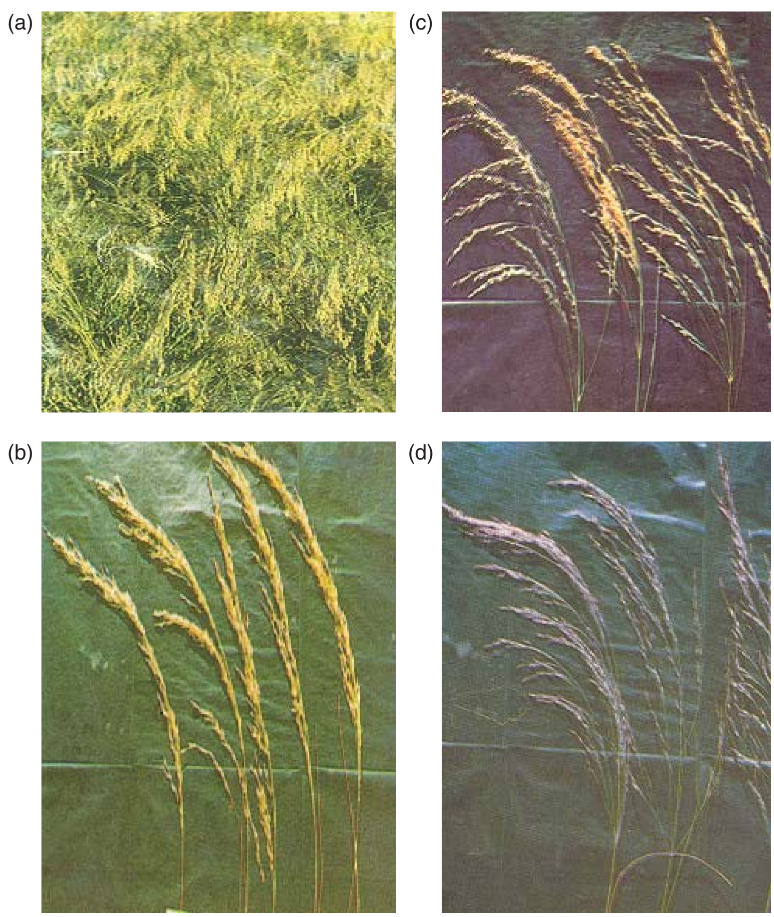

Figure 1 Typical teff field plant and panicles of some teff varieties: (a) teff field of DZ-01-196, (b) panicles of DZ-01-196 (compact), (c) panicles of DZ-Cr-37 (less compact), and (d) panicles of DZ-01-99 (loose). (Reproduced with permission from Tefera H, Ayele M, and Assefa K (1995) Improved varieties of teff [*Eragrostis tef* (Zucc.) Trotter] release of 1970–1995. *Research Bulletin*. 1. Debre Zeit Agricultural Research Center, Ethiopia.)

(in a conical shape, with the panicles towards the center), outdoors, under the shade, till it is ready for threshing.

Threshing is usually done by oxen-trampling or manually with sticks, after spreading the dried panicles on a dry, circular threshing floor. The threshing floor is prepared by smearing cow dung, cement, or other suitable materials. The grain is traditionally winnowed by wafting in the open air, with the help of a rectangular, flat piece of dried leather, called an *afarsa* or *hafarsaa* (O) ($\sim$0.4 m width $\times$ 0.8 m length). Threshers or combine harvesters can also be used. However, grain loss is large because the teff grain has very small size and light mass, and can be easily blown away with the chaff.

In Ethiopia, the grain is traditionally stored in *gotera* (A, T), *gotaara* (O) (small hut-like stores), or pots or sacks. In comparison with other common cereals, teff grain is less prone to attacks by weevils and other storage pests. Thus, it can be safely stored under traditional storage conditions.

Teff Grain Marketing

In local markets of Ethiopia, several small-scale grain traders distribute teff grain from major growing areas to the urban consumers and to regions of shortage in teff grain production. At Addis Ababa, teff grain is marketed in a place called *Ehil berenda* (Markato). At present, international teff grain export is not common. But wherever there is a market, companies (government-owned, joint ventures, and private firms), such as Ethiopian Grain Trading Enterprise and Oromo Development Association, which export oil and pulses have the potential to export teff grain as well.

Physico-Chemical Properties of Teff Grain

Morphology

Teff grain is hull-less (naked) and comes in a range of colors – from milky-white to almost dark brown. The most common colors are white, creamy-white, light brown, and dark brown (Figure 2). The grain is oval-shaped with size 0.9–1.7 mm (length) and 0.7–1.0 mm (diameter). The individual grain mass is generally $\leq$2 mg, $\sim$0.6–0.8% of the wheat grain mass.

Anatomy

Pericarp The outer pericarp is thin, membranous, and is equivalent to the beeswing bran of wheat. The mesocarp and endocarp present in the inner

Figure 2 Grains of different teff varieties: (a) DZ-01-196 (white), (b) DZ-Cr-37 (creamy white), (c) DZ-01-99 (light brown), and (d) South African Brown (dark brown).

surface of the pericarp are fused and appear as a single layer. As in the case of sorghum grain, this fused layer contains some starch granules.

Seedcoat (testa) Next to endocarp is the testa, which is adjacent to the aleurone layer. In some teff varieties, the testa is reported to contain tannins, and is thus presumed to be thick. However, in the varieties that we have analyzed, including brown varieties, we have not found any significant tannin levels.

Aleurone layer The aleurone layer is one cell thick and is rich in protein and lipid bodies.

Germ Like in other small-grain cereals, the germ occupies a relatively large proportion of the grain and is rich in protein and lipids.

Endosperm The endosperm is the largest component of the grain and consists of outer and inner layers. The outer layer is vitreous and contains most of the protein reserves of the endosperm and a few starch granules. The inner layer is mealy consisting mainly of thin-walled cells containing mostly starch granules with a few protein bodies. Teff has compound-type starch granules (Figure 3a), representing the contents of one amyloplast-like rice, oats, amaranthus, and quinoa starches. On milling, individual starch granules are released along with small groups of protein bodies. The protein bodies are individual entities in nature, spherical in shape (Figure 3a) and unlike those of wheat, they do not coalesce to form a matrix.

Teff Grain Chemical Composition

The proximate chemical composition of teff grain is shown in Table 1.

Carbohydrate Carbohydrate content of teff grain is ~73%, of which virtually all is starch. The teff starch properties are given in Table 2. Individual starch granules are very small (2–6 μm in diameter)

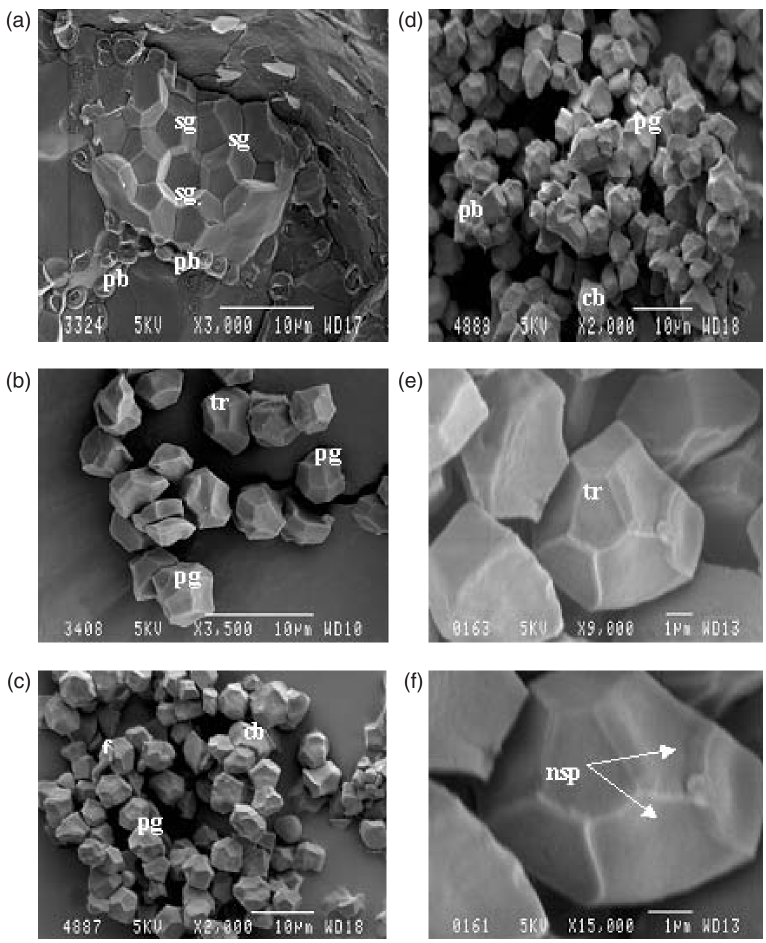

Figure 3 Compound (a) and individual (b–f) starch granules from different teff varieties: (a, b) South African Brown, (c) DZ-01-1681, and (d–f) DZ-01-196 (sg = starch granules, pg = polygonal, cb = cubic, Tr = tortoise-shell, pb = protein, f = fiber, and nsp = no surface pores).

(Figures 3b–3f), similar in size to rice starch granules, but larger than amaranthus and quinoa starch granules. The shape is polygonal, smooth with no surface pores (Figure 3f). A few granules are essentially cubic and at high magnification some appear as tortoise-shell shaped (Figure 3e). The composition of teff starch granules is similar to other normal native cereal starches, with 25–30% amylose. Gelatinization temperature (*Kofler* hot stage and Differential scanning calorimetry (DSC) methods) is high, similar to other tropical cereal starches. X-ray diffraction is A-type of granule crystallinity, ~37%, similar to rice. Pasting temperature is similar to that of maize starch, but cooking time for peak viscosity is longer. Peak, breakdown, and setback viscosities are lower than those of maize starch. The paste clarity of teff starch is opaque. The gel texture is short and smooth. α-Amylase degradation of teff starch granules is by surface erosion and endocorrosion in nature.

Because teff starch granules are very small, smooth, and of uniform size, they offer good functionality as a fat substitute, flavor and aroma carrier, similar to other small-granule starches. Teff starch has good resistance to shear breakdown, and thus it may find good application in high-shear processed foods.

Table 1 The proximate composition (db) of grain teff, *Osborne* protein fractions, and food energy

Biochemical class	*Compound*	*Range (%)*	*Typical value (%)*

Asx is Asp + Asn and Glx is Glu + Gln.

Also, because of its slow retrogradation tendency, it could have attractive applications where starch staling is preferred to be reduced (i.e., in baked and in refrigerated foods).

Fiber The fiber content of teff grain (Table 1) is apparently higher than most other common cereals, because the grain is very small and the bran proportionally large.

Protein and amino acids Typical teff grain protein content (N × 6.25) is ~11%, with a normal range of 9–13%. Thus, the protein content of teff grain is similar to other common cereals. The major amino acids are glutamic acid, alanine, proline, aspartic acid, leucine, and valine (Table 3). Methionine, phenylalanine, and histidine are slightly higher than in most other cereals, but serine and glycine are lower. Lysine and arginine are essentially higher in teff than in most other cereals, except rice and oats. The balance among essential amino acids is similar to the whole edible portion of egg protein, except for its lower lysine content. The overall amino acid profile of teff can be regarded as well-balanced.

Osborne protein fractions of teff grain are shown in Table 1. Glutelins, albumins, and globulins are major fractions. The teff prolamin fraction is lower than in most other cereals, except in rice and oats. The major prolamins of teff are similar to the α-prolamins of maize, sorghum, and *coix*. Teff is thus different from other cereals in having lower prolamins and higher albumins and globulins. Teff protein is essentially free of the type of gluten found in wheat. Because of this, teff grain can be used as an alternative food by consumers allergic to wheat gluten (e.g., for celiac patients). As the main protein fractions (albumins and globulins) are the most digestible types, teff protein digestibility is also presumed to be high. Amino acid compositions of the various *Osborne* protein fractions are shown in Table 3.

Table 4 Microelement composition of grain teff (db)

Microelements (mg per 100 g or μg per 100 g)	*Range*	*Typical value*
Calcium (mg)	104–223	165.2
Chloride (mg)	13	13.0
Chromium (μg)	250	250.0
Copper (mg)	0.7–5.3	2.6
Iron (mg)	4.7–19.6	5.7[a], 15.7[b]
Magnesium (mg)	138–190	169.8
Manganese (mg)	1.6–6.4	3.8
Phosphorus (mg)	378–480	425.4
Potassium (mg)	330–570	380.0
Sodium (mg)	11.8–47.0	15.9
Zinc (mg)	2.0–6.7	4.8

[a] Mean of iron from cleaned, acid and/or water washed samples.
[b] Mean of iron from uncleaned samples.

Ash and minerals The ash content in teff grain (Table 1) is apparently higher than in wheat, rye, maize, barley, oats, rice, and millets, in part because teff grain bran is proportionally large. In particular, calcium, copper, iron, and zinc (Table 4) content is higher compared to that in barley, wheat, and

sorghum. The iron content of traditionally harvested teff grain is especially high (~15.7 mg per 100 g), in part because of grain contamination with the soil during harvest. However, when cleaned (with water and/or dilute acid) the level (~5.7 mg per 100 g) is similar to other cereals. Most teff foods such as *injera* are fermented. Destruction of phytic acid by fermentation is known to contribute to high iron availability in diets where fermented teff foods are the staple. Because of these two factors, iron deficiency disease – anemia, is rare among teff consumers in Ethiopia.

Fat and fatty acids Teff grain fat (Table 1) is lower than, for example, in maize and oats. Thus, teff is different from other small-grain cereals in having low fat even though the germ is large. As in most other cereal grains, palmitic, oleic, and linoleic acids are the major fatty acids (Table 5). Linolenic acid in teff is higher than in maize, sorghum, and wheat.

Vitamins In teff (Table 6), thiamin is typically lower, when compared to wheat, rye, barley, oats, rice, maize, millet, and sorghum. Though riboflavin content is considered to be high, it is nevertheless lower than in rye, barley, and oats. Niacin levels are similar to those in maize.

Table 5 Fatty acid composition of grain teff fat

Fatty acids (%)	*Range*	*Mean*
Palmitic (C16:0)	14.0–16.4	15.9
Palmitoleic (C16:1)	0.1–0.6	0.3
Stearic (C18:0)	3.0–3.7	3.3
Oleic (C18:1)	23.3–24.9	24.0
Linoleic (C18:2)	41.3–46.5	44.2
Linolenic (C18:3)	6.9–9.9	7.9

Antinutrients	
Phytate (mg per 100 g)	707
Trypsin inhibitor activity (TIU g^{-1})	5584

RE is retinol equivalent; TIU is trypsin inhibitor unit.

Processing and Usage of Teff Grain

Cleaning

Normally, the grain is cleaned by manual sifting.

Milling

The cleaned grain is usually dry-milled to obtain whole flour. Traditionally in Ethiopia, this was done by *Wafcho* (A) (T), *wafcoo* (O) (top and bottom hard stones). Today, milling with hand, using hard stone, has been replaced by grist mills run by electric power, and, where electric power is not available, by diesel engine or water power. The grist mill is made up of two abrasive hard-disk stones. During operation, one stone is stationary while the other is rotating. The grain, fed into the center (eye) of the upper stone, is fragmented and ground between the two stones, and flour is issued at the periphery. At present, wet-milling of teff grain for chemical component extraction like starch is not carried out.

Usage

Food made from teff grain is a staple diet for many Ethiopians. Teff is considered to have a better food value than the major grains, namely, wheat, barley, and maize, as it is normally used as a whole grain, i.e., the germ and bran are consumed along with the endosperm. Teff flour is used primarily for making of *injera* (A), *caabitaa or budeena* (O), and *tayeta* (T). The flour is also used to make sweet unleavened bread called *kitta* (A), *bixxille* (O), and *daguwalo* (T). *Kitta* can be consumed as bread or it can be used as an adjunct in traditional opaque beer (*tella* (A), *farsoo* (O)), or local spirit (*katikalla* (A), *araqii* (O)). Porridge (*genefo (A)*, marqaa (O)) can also be made from teff flour. Thin, fermented teff flour batter is used to prepare soup (*muk*, (A)). Unfermented teff flour dough is also used in the preparation of traditional snacks (*dabbo Kolo* (A), *hunkuroo* (O)), where the dough is rolled into small balls and then roasted on a hot griddle. In the USA, teff has been promoted as a thickener for soups, stews, and gravies probably because teff flour paste gives the product a short and stiff texture. Teff grain flour imparts a slight molasses-like sweetness to food products, making its inclusion in porridges, pancakes, biscuits, cookies, cakes, stir-fry dishes, casseroles, soups, stews, and puddings desirable. Processing of teff grain in Ethiopia has been limited to the household level. To date, technologies for large-scale commercial processing of teff grain, for the preparation of foods like *injera* is not well advanced. However, apart from traditional usage, recent reports indicate that teff grains, along

with soybean, chickpea, and other grains, are being used in the baby-food industry.

Teff Grain *Injera* Making

In Ethiopia, *injera* is regarded as the national staple food. A flowchart of *injera*-making process is shown in Figure 4. The process involves fermentation and then baking of the batter.

Fermentation Flour is mixed with water and the dough is kneaded, usually by hand. Fermentation for *injera*-making involves two phases that can last a total of 24–72 h. The first phase starts spontaneously when flour is wetted, due to contaminating microorganisms. Or it can be initiated by addition of *irsho* (A) (T), *raacitii* (O) (yellowish liquid saved from the previous batch fermentation). The initial 18–24 h are notable for vigorous gas evolution and maximum dough expansion. At about 30–33 h an acidic yellowish liquid appears on the dough surface. This phase is characterized by a decrease in gas evolution up to 31 h, an increase in liquid volume up to 48 h, and decrease in pH to below 5.8.

The first phase of fermentation results in a liquid/solid separation after ~24 h. The layer of liquid is then removed. About 10% of the fermenting dough is mixed with water (1 : 3 ratio), boiled (2–5 min), and as a result of starch gelatinization, a dough binder, called *absit*, is formed. The *absit* is cooled and added to the fermentation vat signaling the second phase of fermentation. The second phase (0.5–2 h) is characterized by a short duration of dough expansion and gas formation.

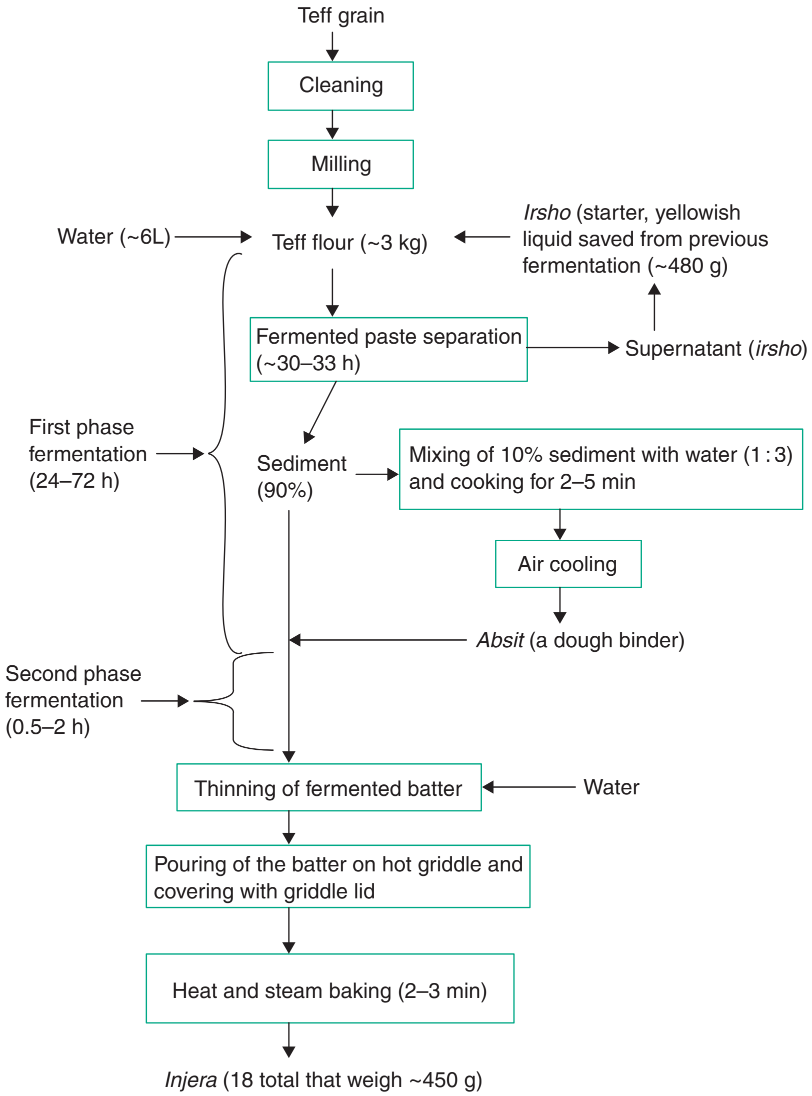

Figure 4 Flowchart of teff *injera*-making process.

During the first phase of fermentation, the yellowish liquid that is removed contains water-soluble nutrients (amino acids, sugars, minerals) and large number of microorganisms involved in the fermentation. This has negative nutritional consequences. Thus, *injera* baked from a batter, after ~31 h of fermentation without discarding the liquid, is recommended as being more nutritious.

A complex group of microorganisms is known to be involved in teff fermentation. Bacteria belonging to Enterobacteriaceae family are thought to initiate the fermentation. During the first 18 h of fermentation, the activities of these bacteria reduce the dough pH to ~5.8. A group of lactic acid bacteria (*Leuconostoc mesenteroides, Streptococcus faecalis, Pediococcus cerevisiae, Lactobacillus brevis, Lactobacillus plantarum*, and *Lactobacillus fermentum*) are involved at the later phase of fermentation (18–72 h) in reducing the dough pH from 5.8 to 3.8. During the later phase of fermentation (22–24 h), yeasts of two genera *Saccharomyces* and *Torulopsis* are reported to be involved. In the later phase (~48 h), yeast belonging to the genera *Candida* and *Pichia* are the dominant types isolated from the yellowish liquid removed from dough. In addition to amylases present in the grain, the bacteria species *Bacillus* sp. A-001 involved in the fermentation has been characterized as one of amylase-producing bacteria involved in partially attacking the starch granules.

In the traditional teff fermentation for *injera* making, commercial yeast is not added externally. The source of the yeast is either from *irsho* or from the endogenous microflora of teff grain, and its flour that grows in the batter after the flour is wetted with water. Therefore, the yeast in the fermentation of teff for *injera* making can be regarded as symbiotic yeast.

Baking *Injera* is usually baked after ~24 h of fermentation. After the fermentation, the batter is diluted slightly with water and then, poured using circular motion from the outer perimeter towards the center, onto a hot-round smooth griddle called a *metad* (A), *eelee caabitaa* (O). It is then covered with a *metad* lid called *akambalo* (A), *qadaada eelee caabitaa* (O) to prevent steam from escaping. The griddle is traditionally made from clay. Before pouring the batter, the *metad* surface is swabbed with ground oilseeds, commonly rapeseed or with animal fat in a piece of cloth. This prevents the *injera* from sticking to the *metad* surface. Depending on the batter thickness, heat intensity applied, and steaming, *injera* can be baked in 3–6 min.

Based on the duration and nature of the fermentation involved, three common types of *injera* are prepared: (1) *injera* made from dough which does not contain *absit*, characterized by a soft, thin, fine appearance, and a sour taste without the "eyes" of *injera* (surface air cells), (2) *injera* made from partially fermented paste (12–24 h fermentation) called *aflegna* (A), *bekuo* (T), characterized by a sweet flavor, pleasant odor, and a rusty red underside, and (3) *injera* made from over-fermented paste called *komtata injera* (A), (T), *qomxoxaa caabitaa* (O) which tastes very sour and is regarded as less nutritious. The thick batter used for *aflegna injera* is also used to prepare a slightly concave, thick flatbread called *cumboo* (O). *Cumboo* is traditionally baked on the preheated surface of a small-size concave griddle, which is placed on a flat larger griddle. Depending on the batter size and heat intensity applied, the baking time for *cumboo* is between 1 and 3 h.

Prospects, Problems, and Recommendations

Teff can be cultivated under harsh environmental conditions where most other cereals are less viable. It has relatively few pest-and disease-related problems in the field. The grain is less prone to attacks by weevils. The nutrient composition of teff grain indicates that it has good potential to be used in foods and beverages worldwide. However, the grain yield of teff is low. The mechanized farming technologies that are used for the production of other cereal grains can be problematic for teff, because the plant stems are very thin and short, and the grain is very small. Manipulation of teff plant genes through research and finding suitable technologies for maximum grain production and harvesting are required.

At present the milling of teff grain is limited to cottage-type millers. Processing of teff for different foods is usually done by traditional ways and is mostly limited to the household level. More research on large-scale milling of teff, processing for different commercial foods, and grain component extraction (e.g., starch) is needed to promote worldwide teff utilization.

TORTILLAS

L W Rooney, R D Waniska, and C M McDonough, Texas A&M University, College Station, TX, USA
S O Serna-Saldivar, ITESM-Campus, Monterrey, Mexico

Introduction

A tortilla is a flat, round, unfermented bread produced from wheat (*Triticum aestivum* L.) flour or lime (CaO)-cooked maize (corn – *Zea mays* L.). Sorghum (*Sorghum bicolor* L.) is used alone or in mixtures with maize for tortillas in parts of Central America. Processing and characteristics of wheat flour and maize tortillas differ considerably. Both types of tortillas originated in Mexico, where they are considered the national bread and are consumed with others foods such as beans, meat, and vegetables. Tortillas, traditionally, are homemade, prepared on a daily basis, and consumed fresh. The technology for maize tortilla production was developed by early Mesoamerican civilizations. Tortillas and "masa" products constitute the staple food for most people in Mexico and Central America. The annual per capita intake in 2001 was 85 kg in Mexico (up to 120 kg in some areas), 6 kg in USA, and 0.3 kg in Europe. The technology for flour tortillas was developed during the sixteenth century in northern Mexico.

Tortillas are increasing in popularity throughout the world. Global sales in 2002 are estimated at \$9 billion for tortillas and \$10 billion for maize

"tacos," "tostadas," tortilla chips, and other corn snacks. Mexico accounts for 42% of the world's production of tortillas, USA 36%, Central America 9%, and other countries 13%. Maize comprises 98% of the tortillas consumed in Mexico and Central America. In Mexico, 40% of the maize is used for tortillas. The tortilla industry is the fourth largest industry (0.90% of GDP) in Mexico. Wheat flour tortillas are more prevalent than maize tortillas throughout the rest of the world. Processing plants for tortillas and alkaline-cooked corn snacks are located on almost every continent.

Wheat Flour Tortillas

All wheat tortillas contain flour, water, fat, and salt. Tortillas prepared using just these ingredients are leavened by steam generated during baking, have dark toast points, and areas which are translucent (i.e., not opaque). These tortillas are common in northern Mexico and are ~1 mm thick, up to 60 cm in diameter, and contain up to 20% fat (on a weight of flour basis). Most flour tortillas outside of Mexico and Central America contain baking powder for leavening to "improve" flavor, opacity, texture (softness, rollability), and shelf life (1 week to 6 months). Tortillas with good appearance, uniform whiteness or opacity, large diameter, and long shelf stability are prepared using chemical leavening agents, emulsifiers, reducing agents, antifungal agents, acidulants, gums or hydrocolloids, sugar, maltodextrins, proteins, and nonactive yeast.

Flour tortillas in Mexico and Central America are usually consumed fresh on the day of production, just as "chapatis," an unleavened, flat bread in India and southern Asia, which is prepared from wheat flour, water, salt, and fat (optional). The formula and processing of flour tortillas in the USA have changed to yield a longer shelf life tortilla, due to the cultural practices of infrequent shopping, refrigerated storage of foods, and preparation and consumption over several weeks. Hot-press, die-cut, and hand-stretch methods are used to form wheat dough into thin disks in the preparation of flour tortillas by the food industry. These methods have replaced the traditional processes of preparing tortilla disks by hand. Each requires different flour specifications, dough preparation, and baking conditions, resulting in distinct tortilla characteristics.

Hot-press tortillas (Figure 1) are consumed as gourmet table tortillas, "fajitas," and soft tacos, and are prepared in restaurants for immediate consumption. Hot-press tortillas have a smooth surface, a tender bite, some elasticity, resist moisture absorption from fillings and have longer shelf stability than other flour tortillas. Hot-press tortillas are the most popular and account for >90% of the retail market.

Die-cut tortillas are mainly used in "burritos," frozen Mexican foods, and fried products, i.e., taco salad bowls, taco shells, "chimichangas," and "buñuelos." Die-cut tortillas often have dusting flour on the surface, lower moisture content, a pasty mouthfeel, and are less resistant to cracking during storage. The die-cut method greatly reduces the cost of production of tortillas.

Hand-stretch tortillas are consumed as table tortillas, burritos, and used to prepare certain fried products. Hand-stretch tortillas have dusting flour on the surface, irregular shapes, moderate elasticity, and a firmer bite than hot-press tortillas. They are more costly to produce and are decreasing in popularity.

Tortilla dough is mixed to incorporate microingredients, fat, and water into the flour and form a pliable, extensible dough (Figure 1a). The optimum dough temperature should be 32–34°C after mixing and gluten development. Dough properties are primarily modified by flour quality, levels of reducing agent, emulsifier, fat and water, and dough temperature. The dough is rested 0–20 min (Figure 1c) before being divided and rounded into dough balls (Figure 1b) for the hot-press and hand-stretch procedures. The dough balls are rested in a warm, moist environment for 2–20 min (Figure 1c) to relax the gluten network. Rested dough balls form larger diameter tortillas with more opacity and longer shelf stability. Tortilla dimensions (thickness, diameter), opacity, and shelf stability are affected by the hot-pressed dough ball's pressure, temperature, and duration of hot-pressing (Figures 1d and 1e).

In the hand-stretch procedure, the dough balls pass through two pairs of rollers, set perpendicular to each other, prior to stretching by hand on a hot griddle and baking. The dough for hand-stretch and die-cut tortillas is dusted with flour to prevent adhesion to equipment. The dough, in die-cut operations, is pumped and shaped into a sheet that is further thinned by a series of rollers and cross-rollers on a moving belt. The thin sheet of dough (0.5–2.5 mm) is cut by a circular die, which forms the tortilla shape. The scrap dough is returned to the dough pump and reprocessed.

The formed tortilla disks, regardless of the process, are baked (190–260°C for 18–50 s) in gas-fired ovens (Figure 1f) that usually have three tiers. Oven conditions vary depending upon tortilla thickness, type of conveyor (slat or wire), and method of preparation. Puffing of the tortilla occurs near the end of baking and is common in hot-press and hand-stretch tortillas. Tortillas are typically "cooled" to <32°C on conveyors (Figure 1g) for 2–5 min prior to packaging

Figure 1 Processing of flour tortillas using the hot-press method. Note: (a) = tortilla dough (D) in bowl with dough hook (H); (b) = dough balls; (c) = resting chamber for dough and dough balls; (d) = dough ball moving on teflon belt into the hot-press (P) behind inset area (I; arrow indicates press); (e) = pressed disk moving on teflon belt immediately after hot-pressing (arrows indicate direction of movement); (f) = tortilla at the end of the first tier of a three-tier oven; (g) = tortillas on wire conveyer; and (h) = stack of flour tortillas.

in plastic bags. Moisture and heat are lost during this operation. Improper cooling increases not only the microbiological problems but also the "stickiness" of the tortillas.

Fresh tortillas (Figure 1h) have a soft and pliable texture which changes to a firmer and less extensible texture during storage. Improvements which make it possible to retain the freshness of hot-press tortillas

throughout the storage period are naturally preferred. About 80% of flour tortillas are prepared using the hot-press method even though the die-cut method is more efficient. Hot-press flour tortillas are the preferred "bread" in the Space Program because of their versatility, functionality, long shelf stability, and lack of crumbs. Consumers prefer hot press tortillas because they retain their freshness during storage. Nontraditional fillings for breakfast, lunch, dinner, and desserts increase their versatility and convenience.

Wheat flour requirements are determined by the desired tortilla characteristics, the formula, processing conditions, and equipment. Wheat flour is usually hard wheat flour with a protein content ranging from 9.5% to 12.5%. Flours for hot-press and hand-stretch tortillas generally contain less protein and gluten strength than flours for die-cut tortillas. Tortillas that are made with flours with poor gluten strength remain pliant for only a couple of days. Hot-pressed tortillas which are made with good-quality flours are generally ones with smaller diameter, less opacity, and tend to remain more pliant during storage. Flour ideal for hot-pressed tortillas has intermediate gluten strength and levels of protein quality with small amounts of damaged starch.

Water (45–55% of flour weight) is a reaction medium for gluten formation and chemical reactions (leavening) during mixing. Low levels (10–80 ppm) of reducing agents, such as sodium metabisulfite or cysteine, reduce dough mixing time and increase the extensibility of dough during hot-pressing, which yields larger diameter tortillas. Salt (1–2%) is added for taste and to strengthen the gluten complex. Baking powder (0.05–2.5%) causes tortillas to have a less dense, spongy structure, i.e., increased whiteness or opacity and greater specific volume. The high dough temperatures (25–40°C) cause premature leavening reactions during mixing and less leavening is available during baking. Leavening acids and bicarbonates that dissolve more slowly and react to form CO_2 during latter stages of baking improve tortillas opacity and thickness. Various natural and modified cellulose gums are added at 0.1–0.5% levels to improve dough machinability and decrease the stickiness of baked tortillas.

Solid or liquid fats (3–20% of flour weight) are added to improve dough properties by weakening gluten strength. Fats also contribute to softer and more flexible tortillas by limiting amylose retrogradation during storage. Dough-strengthening emulsifiers, such as sodium stearoyl-2-lactylate, improve dough cohesiveness and integrity of the outside perimeter of hot-press tortillas. Emulsifiers, such as glycerol monostearate, limit amylose retrogradation and improve tortilla softness. Low-fat (< 3 g fat per serving) and fat-free (< 0.5 g fat per serving) flour tortillas have been developed; these have proved to be extremely popular with sales exceeding $40 million in the USA in 2002.

Antimicrobial agents (propionates, sorbates, or mixtures thereof) limit fungal growth and extend shelf life and are used at 0.2–0.6% of flour weight. Optimum antifungal activity occurs at less than pH 5.5. Tortilla pH is lowered by acidulants (citric, fumaric, phosphoric acids). Soluble acids, however, cause the early release of CO_2, hence granular fumaric acid or fat-encapsulated acids are commonly used to delay their solubility so as not to interfere with leavening reactions.

Lime-Cooked Maize Products

Three basic types of products are industrially produced from lime-cooked maize: table or soft tortillas, corn chips, and tortilla chips. Corn and tortilla chips are primarily produced and consumed in developed countries, where they have an important share of the salted snack-food market. Sales of corn and tortilla chips in the US in 2002 totaled $5.7 billion. Modern production of tortilla chips and corn chips have evolved into specialized processes. They are quite different from the orginal tostadas made by frying stale, maize table tortillas.

Table Tortillas from Maize

Tortillas are produced using traditional and industrial processes. Maize (Figure 2a), lime, and water are three basic ingredients needed for the production of masa. In the traditional process, maize is lime-cooked in clay pots over a fire, followed by steeping for 8–16 h. The cooking liquor, called "nejayote," is discarded; then, the "nixtamal" is hand-washed and ground into a fine masa with a stone grinder. The masa is hand-molded or pressed into disks which are baked on a hot griddle or "comal." The tortilla disks are baked on each side to seal the surfaces and form steam that causes the tortilla to puff. Traditionally tortillas are produced on a daily basis. Tortillas vary in thickness from different localities in Central America and Mexico. Fresh maize tortillas have an outstanding flavor and texture, which firms rapidly into an unacceptable product. In Mexico, the bulk of tortillas are consumed fresh daily and leftover tortillas are fried into tostadas and "totopos." Tacos are soft tortillas wrapped around meat, sauces, beans, and other fruits and vegetables in Mexico. The tacos in the US, however, are deep-fried tortillas in a U shape, filled with meat, sauces, etc. Other masa-based products include "tamales," "atoles," and "pozol" which is a fermented masa.

Figure 2 Processing of maize into tortillas and tortilla chips. Note: (a) = kernels of maize illuminated from behind, the light areas indicate the hard, vitreous endosperm (H) while the darker areas indicate the soft, floury endosperm (S) and germ (G); (b) = maize entering cooking water containing calcium oxide; (c) = cooked maize or nixtamal with adhering partially hydrolyzed pericarp (HP) before the washing step; (d) = separated grinding stones with nixtamal (center, n) and masa (outside edge, m) in the grooves (arrow); (e) = stone-ground masa; (f) = sheeting rollers forming disks of masa and a wire mesh belt transferring the disk to the oven (arrow indicates direction of movement); (g) = tortilla oven with a tortilla (T) on the third tier leaving the oven; (h) = tortillas cooling on a wire conveyer; (i) = stack of maize tortillas.

A popular Mexican soup, "posole," is made from the large, soft, nixtamalized maize kernels.

The industrial tortilla process begins when the maize is lime-cooked in agitated open baths, vertical cookers, or steam kettles (Figure 2b). The grain is generally mixed with three parts water and 1% lime, based on grain weight, and cooked for 15–45 min at temperatures ranging from 85°C to 100°C. The nixtamal is then steeped for 8–16 h in the hot lime solution. After steeping, the cooked maize or nixtamal (Figure 2c) is pumped with the steep liquor or dropped by gravity to washers. The cooking

liquor is drained and the nixtamal washed with pressurized water. Most of the pericarp and lime is removed during this step. The washed, cooled nixtamal is ground using two radially-carved, volcanic or synthetic (aluminum oxide) stones (Figure 2d) or stainless-steel plates. One stone is stationary and the other rotates at 500–700 rpm. Masa particle size is directly related to the gap and pressure between the stones and the size, depth, and pattern of the grooves. During grinding, the nixtamal is disrupted into an array of particles from starch granules (10 µm) to endosperm pieces (2 mm). Some starch granules are gelatinized and dispersed by the friction of the stones to produce the glue-like material that causes cohesiveness in the masa. Only a small amount of gelatinization of the starch occurs during cooking and steeping. Grinding produces most of the gelatinized starch that holds the particles of masa together during subsequent pumping and sheeting into unbaked tortillas.

The ground particles (Figure 2e) drop into a masa feeder with augers (masa hog) which move the masa to above the sheeter head. The two rollers of the sheeter compresses the masa into a thin layer, which is die-cut into standard size disks, strips, triangles, etc., depending upon the products desired. These formed pieces of masa (Figure 2f) are transferred by mesh belts into a three-tier, gas-fired oven (Figure 2g) to bake on lime-coated, metal slats or mesh belts at 280–302°C for 30–45 s. The tortillas are allowed to cool on open conveyors, counted, stacked, and packaged (Figures 2g and 2h).

Tortillas are formulated with antifungal compounds or by raising the pH to improve their shelf life when merchandized for 3–90 days. Antifungal compounds, sorbates and propionates, along with acidulants are incorporated during grinding or masa kneading. The pH must be reduced to enable the preservatives to function properly. Alternatively, tortillas are preserved by the lime that is not removed during washing. High pH is an effective preservative, if the tortilla pH is greater than 9.8. Tortilla pieces that are fried immediately do not need preservatives; however, those fried after ambient or refrigerated storage are acidified and preserved.

About 40% of the maize tortillas consumed in Mexico are prepared using dry masa flour. More than 2 million metric tons (Mt) of dry masa flour for table tortillas are produced annually in Mexico. These flours are transformed into ~3.4 Mt of table tortillas. Dry masa flour is produced by cooking corn with alkali, coarsely grinding the nixtamal with a modified hammermill, drying, and then, sifting. The masa is dried in large tunnels, or drying towers, in which warm airflows countercurrently over the ground particles. The particles too large for masa flour are ground by hammermilling, sifted, and the various paricle sizes are blended in the correct proportions to produce various dry masa flours for specific products with different particle size, color, pH, and water uptake. The quality and consistency of these products have improved over the years. The particle size of masa for table tortillas is finer because the tortillas hopefully will puff during baking. In the case of fried snacks, the coarser particles in dry masa flour allow water vapor to escape during frying which improves chip texture. High-quality tortillas and chips are prepared from dry masa flours. A blend of dry masa and fresh masa is sometimes used in many tortillerias. Dry masa flours for table tortillas are usually enriched with thiamin, riboflavin, niacin, folic acid, iron, and zinc.

The use of dry masa flour depends upon the processor. However, many new processors use dry masa flour because of its convenience, even though it costs 2–3 times as much as raw maize. Dry masa flour does not require experienced personnel, space, or equipment to cook, steep, wash, and grind maize, or the expense of effluent disposal. The dry masa flour is shelf stable if it contains less than 10% moisture and only requires water and mixing to form masa. Dry masa flours are mixed with 1.0–1.2 parts water for ~3–5 min to produce a suitable dough.

Dry masa flours usually produce masa with less adhesiveness and higher viscosity, requiring more force on the rollers to form a thin sheet. Properties of rehydrated masa can be changed by modifying cooking and frying procedures or by addition of 0.1–0.7% carboxymethylcellulose. Carboxymethylcellulose makes table tortillas more chewy and improves tortilla flexibility during storage. Vital wheat gluten when added at 0.5–2% improves retention of tortilla flexibility during storage. Other hydrocolloids also increase masa softness but usually not tortilla flexibility. Product-softening emulsifiers, when used at less than 0.5%, do not usually improve table tortilla quality. Specific amylases soften masa and tortillas and improve processing and product qualities. Combinations of these additives are common in tortillas.

Fried/Snack Products

Frying has expanded the market for masa-based foods because the final products have excellent organoleptic properties and long shelf lives. Two popular snacks from masa are corn chips and corn tortilla chips. Corn chips are produced by directly frying extruded or sheeted masa pieces, while masa for tortilla chips is formed into triangles, strips, or circles, baked, equilibrated, and fried. Tortilla chips have less oil, a firmer texture, and a stronger maize flavor than corn chips.

Nixtamal for these snack foods is cooked and not steeped as much as the nixtamal for table tortillas. The nixtamal for fried snack-foods is ground into coarse masa because the larger particles in the sheeted pieces allow steam to escape through many small pores that develop during baking and frying. This prevents the formation of serious quality defects, such as oily appearance, pillowing, or blistering.

Corn chips are prepared by extruding masa through a die, which is cut by rotating knives before frying or by sheeting and cutting into strips. Corn chips have a more friable texture than corn tortilla chips and contain more oil than tortilla chips (Table 1). Products from white maize are fried at higher temperatures and shorter times than those from yellow maize. Beta-carotenes in yellow maize degrade into beta-ionones which are bitter and off-colored. Frying temperatures and times range from 165°C to 195°C for 20 to 90 s, depending upon maize properties. A blend of yellow and white maize is normally used for corn chips.

The moisture content of the masa or tortilla is related to the oil absorption during frying. Specifically, the higher the moisture, the higher the oil absorption. As moisture leaves the cooked product during frying, oil is absorbed into and onto the structure of the fried food. The appearance and texture of chips are also affected by masa particle size distribution, tortilla baking and equilibration, structure in the piece to be fried, maize color, and oil quality.

Corn and tortilla chips are salted and flavored immediately after frying. The hot chips are conveyed into an inclined rotating cylinder where the flavorings are applied. The most popular flavorings include nacho cheese, hot and spicy, barbecue, French onion, lemon and salt, and jalapeño. Corn and tortilla chips are packaged in moisture-proof aluminized bags, flushed with nitrogen to protect the product physically and to limit oxidative rancidity.

Specialty products include blue chips and reduced-fat snacks. Blue maize tortilla chips, served in specialty restaurants, are available as organic and regular products. Blue maize has a pigmented aleurone that imparts an intense blue color. It has high levels of flavanoids and other phenolics that may have nutraceutical properties.

Reduced-fat snacks can be achieved by processing or by using a fat-replacer. Baked, low-fat tortilla chips are prepared using air impingement, infrared, and/or microwave ovens. Olestra, a nonabsorbed fat, is utilized to fry tortilla chips and reduce fat content and calories. Sales of low fat and Olestra-fried chips have decreased apparently because consumers prefer the taste and texture of full-fat products and/or dislike the perceived gastric side-effects. The trends toward organic and natural health products are continuing with a wide variety of organic chips available.

Chemistry of Nixtamalization (Alkaline Cooking)

Cooking and steeping maize in lime solution (pH > 11), softens the pericarp, hydrates the endosperm, partially solubilizes proteins and cell walls, facilitates starch swelling, and gelatinizes only a small amount of starch. Significant dry matter is lost in the steep solution especially soluble proteins, sugars, and other components. The breakdown of the cell walls of the pericarp forms gums which are useful in table tortillas. However, for snacks the partially solubilized pericarp is removed by washing, as these pieces cause processing problems. The cooking and steeping times vary depending upon the desired products, equipment used, and the maize quality.

The quality of maize for alkaline cooking is critically important to produce high-quality products. Whole, sound, mature kernels of maize with a high proportion of hard to soft endosperm (Figure 2a) yields more masa and tortillas after nixtamalization. Uniform flat kernels without cracks and broken kernels and intermediate to hard endosperm are preferred. Pericarp removal is affected by genetics and by the environmental conditions during maturation of the maize.

The maize must be cooked uniformly to provide adequate hydration and partial solubilization so that grinding produces a nonsticky, cohesive masa that can be formed into a thin disk and baked into a desirable tortilla or fried into chips or tortilla chips. During cooking and steeping, the pericarp is converted into gums and insoluble materials. These materials are washed from nixtamal before grinding, especially when prepared into fried products; however, nixtamal for maize table tortillas is not washed as much, since the gum binds water and improves the texture of tortillas. In tortilla chips, the partially hydrolyzed pericarp causes discoloration and darkening of tortillas. However, extra washing increases dry-matter losses and sewage charges since the dry-matter losses range from 5% to 10% or higher of the original maize depending on the maize quality and the processing parameters.

Table tortillas are excellent when fresh but become rigid after 4–8 h. Firming or staling of tortillas is affected by pH, extent of cooking, moisture content, and storage conditions. Alkaline tortillas retain softness and flexibility longer than regular tortillas because starch retrogradation is inhibited by the many negative charges on the starch chains at pH > 9. Many tortillas are acidified (pH 5.0–5.5) to activate the preservatives, but starch retrogradation and staling are not inhibited

at this pH. Individually or in combination, addition of carboxymethylcellulose, vital wheat gluten, amylases, and waxy maize (100% amylopectin) produces tortillas that retain flexibility longer than normal tortillas. Softness and flexibility of tortillas containing soy flour, barley flour, or beta-glucans from barley flour were retained longer than normal tortillas. The use of emulsifiers, neutral gums, shortening, and modified starches were less effective in limiting firming of tortillas.

Quality of end products depends on the nature of manufacturing practices and of raw materials. Specific types of maize hybrids are approved for use in alkaline cooking by processors. Yellow and white maize, or mixtures thereof, are commercially manufactured into alkaline products. Food maize suppliers arrange for producers to grow, harvest, store, and deliver clean maize to processors. Premiums are paid to producers to secure maize that is acceptable in terms of kernel hardness, size, cracks and brokens, pericarp removal, and levels of aflatoxins and fumonisins. The ideal grain should be clean, sound, large, uniform, bright-colored, free of cracks, and broken kernels, high test weight with intermediate-to-hard endosperm. In addition, the kernels should have a rounded crown and a shallow, unwrinkled dent, and the pericarp should be easily removed during lime-cooking. Broken and cracked kernels cause increased dry-matter losses and poor-quality (sticky) masa. The environment affects corn quality significantly. Anything that affects the kernel during maturation affects the processing properties of the grain.

Nutritional Value

The nutrient composition of some lime-cooked maize foods is compared with white pan bread and wheat tortillas in Table 1. Tortillas, especially wheat flour tortillas, are commonly used as a substitute for pan bread by many people. Flour tortillas are higher in gross and digestible energy because their formula contains more shortening (5–15% based on flour weight). Whole meal flour tortillas have higher amounts of fiber, protein, and ash than do white flour tortillas.

Maize tortillas are the main source of energy, protein, calcium, and other important nutrients in Mexico and Central American diets. Lime-cooking considerably increases calcium and the bioavailability of niacin, and significantly decreases the amount of aflatoxins and fumonisins in contaminated maize.

The caloric densities of corn chips and tortilla chips are significantly higher than table tortillas because of the oil absorbed during frying and their low post-processing moisture contents. Tortillas and snacks produced from enriched dry masa flour contain higher levels of B-vitamins, Fe, and Zn than counterparts produced from fresh masa. In Mexico, dry masa flours are enriched by government regulation; some of

these flours are optionally fortified with 5% soy flour. Human nutritional studies have demonstrated that fortified and enriched flours significantly upgrade the nutritional status of low-income people, especially children. Quality protein maize (QPM), which contains 50% more lysine and tryptophan, is processed into tortillas in some areas of Mexico. The tortillas have improved protein quality but limited production of QPM restricts its application.

TRITICALE

B J Furman, University of California, Davis, CA, USA

Introduction

Triticale is the first man-made cereal grain crop species resulting from the hybridization of wheat (*Triticum*) with rye (*Secale*), the name of which combines the scientific names of the two genera involved. This synthetic amphiploid is obtained by chromosomal doubling after artificial crossing to produce fertile hybrids. It is a small-seeded cereal grain that is used for both human consumption and livestock feed. As a hybrid species, it combines many of the better qualities of both of its parents. Triticale possesses wheat's properties for food production and rye's adaptive properties, and under certain conditions can

out-yield both parents. This promising crop species is grown on more than 3 million hectares (Mha) worldwide. Furthermore, triticale is an important germplasm source for wheat improvement, providing a vehicle to transfer desirable rye characteristics to wheat.

Origin and Types

The Scottish scientist Alexander Stephen Wilson produced the first triticale in 1876. Triticale was initially developed to combine the positive traits of both parent types: the vigor and winter hardiness as well as the higher protein content of rye combined with the higher-quality gluten and baking properties of wheat. However, initial progress was limited by the fact that resulting hybrid progeny was sterile. In the 1930s, the discovery and use of the chemical colchicine, a natural chemical extracted from the autumn crocus plant to create chromosome "doubling," overcame this sterility problem. In 1938, Arne Müntzing from Sweden applied colchicine to wheat/rye hybrids, obtaining fertile plants. Once a fertile hybrid was established, it became possible to utilize modern plant-breeding methodologies. Early varieties were primitive and had numerous agronomic disadvantages such as low grain yield, poor seed set, shriveled grain, excessive height, low germination, and late maturity. Triticale improvement commenced in the 1960s to create new and better combinations between wheat and rye, triticale and triticale, and triticale and wheat. Most notable were breeding programs at the International Center for Maize and Wheat Improvement (CIMMYT) in Mexico and the University of California at Davis (UCD) for spring triticales and programs in Poland and the University of Manitoba, Canada for winter varieties.

There are two main types of cultivated triticales: octoploid types produced from the hybridization of bread wheat, *Triticum aestivum* L., with rye, *Secale cereale* L., and hexaploid types using durum wheat, *T. turgidum* L., followed by chromosome doubling of the hybrid plant (Figure 1). Octoploid triticales ($2n = 56$) contain the A, B, and D genomes of bread wheat and the R genome of rye, while the hexaploid triticales ($2n = 42$) contain the A and B genomes of durum wheat and the R genome of rye. However, most triticale cultivars are hexaploids. There is a third type of triticale ($2n = 28$) produced from the hybridization of diploid wheat, *T. monococcum* ($2n = 14$) with rye, but is not considered to be important economically. Although triticale is a cross between wheat and rye, it is self-pollinating (similar to wheat) rather than cross-pollinating (like rye). Most agronomically desirable triticales that breed true have resulted from several cycles of improvement, and are primarily from the durum–rye crosses with some common wheat parentage occasionally involved.

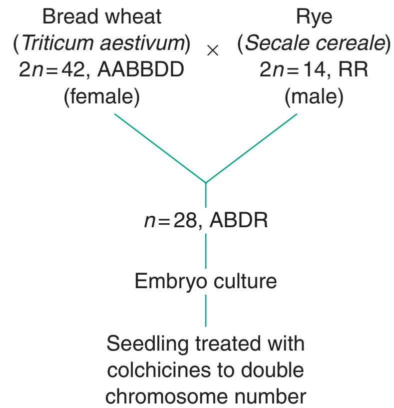

Figure 1 Flow diagram for octoploid triticale development showing chromosome number and genome identifications. The hexaploid type ($2n = 42$) is produced similarly, though using durum wheat (*T. turgidum*, $2n = 28$, AABB) as the female parent. (Adapted with permission from Qualset CO (2002). Triticale. In: *McGraw Hill Encyclopedia of Science and Technology*, 9th edn. The McGraw-Hill Companies, Inc.)

In general, triticales can be divided into three groups (Table 1):

1. "Primary triticales" are the initial product of the wheat × rye hybridization followed by doubling of chromosome numbers to produce the hexaploid or octoploid types.
2. "Secondary triticales" are produced by intercrossing primary triticales or by crossing a primary triticale with wheat.
3. "Substituted secondary triticales" are hexaploid with A, B, or D genomes of wheat substituted for one or more R genome chromosomes of rye.

Primary triticales are often found to be fragile, poor producers, and genetically unstable. They are used as breeding stock to produce the more stable and agronomically favorable secondary and substituted secondary triticales. Secondary triticales can be either hexaploid or octoploid and often contain complete genomes of wheat and rye, whereas substituted triticales never have complete rye genomes (Table 1). One advantage of the secondary hexaploid triticale is increased genomic diversity, resulting from the insertion of portions of the D genome from the hexaploid wheats. Spike type is often used as a visual morphological marker to distinguish types. Octoploid triticale spikes appear similar to wheat spikes, whereas hexaploid triticales have more distinctive spike types (Figure 2), and are classified as Beagle (for complete triticales) and Armadillo (for substituted triticales).

Table 1 Development and examples of primary, secondary, and substituted triticales

Figure 2 Spike types representing substituted (left, Armadillo) and complete (right, Beagle) forms of triticale.

Adaptation and Production

Triticale is grown using cultural practices similar to wheat and rye. However under some conditions, earlier planting can result in better yields. It works well planted alone, as a companion crop for establishing alfalfa and for interseeding into established alfalfa, and as a double crop with corn and other summer annuals. There are both spring and winter growth habits depending on the parents used in the cross, with environmental requirements similar to other winter and spring sown cereal grains. Drought tolerance is

Table 2 Desirable characteristics of wheat, rye, and triticale[a]

Wheat	*Rye*	*Triticale*
High-yield potential	Many grains per ear	High yield
Large, filled grain	High biomass	High-quality straw
High harvest index	Low-temperature growth	High feed value
Tillering efficiency	Winter hardiness	Disease resistant
Short straw	Drought tolerance	Stress tolerant
Sprouting resistance	Disease resistance	Winter hardiness
High-energy grain	Grain high in lysine	High lysine content

[a]Modified from Semundo Limited (1994) *Triticale The Hybrid Evolution*. Cambridge: Semundo Limited.

the primary advantage that spring triticales have over other spring cereal crops. Winter triticale provides a high-yielding early maturing alternative to spring triticale for short-season areas. The University of Manitoba began the first intensive program in North America in 1953, working mostly with durum wheat–rye crosses. Since then, triticale has been the subject of modern plant breeding efforts for and has resulted in excellent gains in yield and quality. Triticale most closely resembles its wheat parent but exhibits more vigorous growth characteristics. As a hybrid species, it contains many of the better traits from each parent (Table 2). Triticale can combine the bread-making qualities of wheat with much of rye's adaptive properties such as disease resistances, drought tolerance, and adaptability to harsh soil conditions. As a result, varieties have been produced with a wide adaptive range as well as site-specific adaptation. Triticale does well in regions where wheat performs poorly, such as cold and infertile soils, extremely sandy soils, soils with high levels of boron, salty soils, acidic soils, manganese-deficient soils, and dry soils. One particular concern, however, is the presence of ergot infection (caused by the fungus *Claviceps purpurea*) in some areas.

The first commercial triticale cultivars were released in 1969. Today triticale is becoming a crop in its own right and is grown on over 3 Mha worldwide and in at least 27 countries (Table 3). This crop contributes more than 10 Mt year^{-1} to global cereal production. Since its introduction, the area harvested has increased over 7 times and amount harvested has increased over 18 times (Figure 3).

Although it is grown throughout the globe, the countries that produce the most triticale are China, Poland, and Germany. There is also significant production in Canada and United States.

Usage

Use of triticale for human consumption has not yet become widespread. Although triticale flour and products are available commercially (namely in specialty markets such as health food stores), this availability is limited. It comes in several forms including whole berry, flakes, and flour. Whole triticale can be cooked and used in a variety of dishes. Quality evaluations have shown triticale grain inferior to wheat for milling and baking, making large-scale commercial baking not feasible. Triticale flour is low in gluten, and bread made from it alone is heavy. For that reason, it is usually combined half-and-half with wheat flour. If mixed with wheat or rye flour, triticale flour can be used to make a number of breads and pastries. In developing countries, triticale flour is often mixed with wheat flour during wheat shortages. It is of course important that the crop is not infected with ergot, as this is highly toxic to humans.

Most triticale production is used for animal feed. It offers better amino acid balance, lysine content, and higher protein, particularly important for swine and poultry. However, triticale has lower energy content than other grains, and feeding of triticale must be supplemented with other grains. It can also be used as forage, silage, or hay for ruminants, offering high

digestibility and out-yielding traditional crops in dry soils. Care should also be taken to insure that the crop is not infected with ergot.

Alternative uses of triticale include use as a cover crop to prevent soil erosion and land reclamation. Triticale has also been used in limited amounts as raw material in bioethanol production. Ethanol plants pay a premium for triticale over barley, since it has more starch and no hull, making alcohol production more efficient.

Genetic Resources

As a synthesized species, triticale has no wild ancestors and there are no existing landrace varieties. In addition, the actual wheat and rye parents used in triticale synthesis are often either unknown or no longer available. It is therefore often not possible to resynthesize unique triticale genotypes through hybridization. Genetic resources for the development and enhancement of triticale include existing triticales, wheat and rye, and the ancestral species of both wheat and rye. Itself, triticale exists as a genetic resource for the improvement of wheat, providing a vehicle to transfer desirable characteristics from rye.

In order to insure continued improvement in triticale, it is important to maintain a comprehensive genetic resource collection. CIMMYT has established a world gene bank for triticale and has over 15 000 accessions. The North American triticale genetic resource collection was evaluated at the UCD and showed a great deal of variation in both qualitative and quantitative traits. The collection is now maintained at the USDA Small Grains Collection in Aberdeen, ID, and at CIMMYT in Mexico.

Future Prospects

Triticale production has increased tremendously since the 1970s and genetic improvements have been vast. It can only be expected that improvements will continue, especially with the tools provided by biotechnology. *In vitro* regeneration of plants will allow for successful genetic transformation. Genomic maps for wheat and rye have been completed and will provide invaluable assistance for marker-aided selection.

Although used primarily for animal culture, it holds promise on a number of additional levels. Perhaps one of triticale's greatest potential is as a vehicle for gene exchange for wheat improvement, extending wheat's gene pool. It, however, still holds promise to be a leading food crop in some areas of the world. Continual improvements are being made to increase triticale's grain quality for commercial production. There is a great deal of potential for triticale products in the specialty markets, especially in the west where a healthier and more varied diet is becoming increasingly popular and commercialized. Triticale also has potential for increasing global food production in developing countries. It grows in many areas unsuitable for wheat production and can out-yield wheat in certain areas. Already used in many of these countries to some degree, increased production for food would likely find a market, especially in areas where wheat shortages are prevalent. Triticale may also play an ecological role in the future, both for soil reclamation and biogas usage.

V

VARIETY IDENTIFICATION OF CEREAL GRAINS

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The need to identify varieties and species of grains arises because they may be significantly different in their genetic traits with respect to grain-quality attributes and according to their agronomic potential, e.g., resistance to pathogens. Therefore, it is important that there should be adequate means available to permit distinction to be made between these various genotypes (genetically different forms). This article summarizes the range of methods in use and under development for routine identification of cereal varieties.

The need for variety identification arises especially at the stages of sowing and harvest. The farmer needs to insure that the seed being planted is of the correct genotype, and the grain buyer needs assurance at harvest that the quality type of the grain is appropriate for the planned utilization.

Variety identification is especially needed for wheat, because of the wide range of quality types available. The examples in Table 1 include two hard-wheat varieties suited to conventional bread production (Marquis and Gabo) and a soft wheat (Rosella), whose weaker dough properties make it suitable for making cookies and cakes. The varieties Marquis and Gabo are very old wheats, now superseded by varieties with better resistance to rust and superior yield potential. Furthermore, these two wheats themselves are examples of families of wheats adapted to very different growth environments, namely, spring sowing after the winter of the Canadian prairies (Marquis) versus the moderate climate of the wheat belt in northern New South Wales, Australia. These three examples, all of the same genus and species, must in turn be distinguished from durum wheat, which is a different species, suited specifically to the manufacture of pasta products.

Historical Background

Variety identification often involves the need to make subtle distinctions among plants or grain samples of similar appearance. The need for such distinctions has arisen since the early twentieth century as a result of the efforts of plant breeders to produce genotypes suited for specific niches of agronomy, climate, and quality type. At the turn of the twentieth century, there was poor knowledge about distinctions between genotypes within grain species. Seed for sowing may have contained a range of genotypes, due to poor

Table 1 Examples of different species and varieties of grain

Common name	*Genus and species*	*Variety (date of release)*	*Characteristics*
Bread wheat	*Triticum aestivum*	Marquis (1911): at least two biotypes	A hard red spring wheat of good bread-making quality adapted to the Canadian prairies
Bread wheat	*Triticum aestivum*	Gabo (1945)	A good baking white-grained wheat adapted to the Australian prime-hard region
Bread wheat	*Triticum aestivum*	Rosella (1986)	An Australian soft white wheat suited to biscuit manufacture
Durum wheat	*Triticum turgidum*	Tamaroi(1998)	A very hard grain, suited for pasta manufacture
Malting barley	*Hordeum vulgare*	Clipper (1968)	A two-row barley, grown in Australia for malting purposes
Feed barley	*Hordeum vulgare*	Cape (from South Africa, about 1900)	A very old six-row variety, not suitable for malting, once grown in Australia for animal feed
Maize	*Zea mays*	StarLink	Maize, genetically modified to provide herbicide resistance

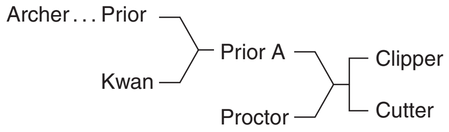

Figure 1 Pedigree chart of two malting barley varieties, illustrating their descent from a cross between Proctor and Prior A, which in turn came from the earlier cross (Prior × Kwan) and selection from Archer.

attention to the need to select at least for uniformity of plant and grain appearance. Mixtures of seed types also arose as a result of neglect in failing to keep different types separate.

Early attempts to produce improved varieties involved the selection of superior plants from an otherwise varied crop, to permit the separate propagation of genotypes that showed, for example, well-filled heads or resistance to pathogen attack. Improvement by selection is illustrated in Figure 1, by the selection of the malting barley Prior (released in Australia in about 1900) from the traditional English barley Archer. Individual farmers often practiced this approach, passing on their improved variety to neighbors and selling the seed on a wider scale. The introduction of cross-pollination, a century or so ago, greatly increased the genetic diversity from which to select improved genotypes.

Varieties and Other Taxonomic Levels

Cross-breeding is illustrated in Figure 1 by the production of two Australian malting barleys, Clipper and Cutter, released respectively in 1968 and 1975. They are "sister lines," being separate selections from the same cross, involving an old English variety Proctor (named in 1952) and Prior A, from the cross between the varieties Kwan and Prior. The task of distinguishing between these sister lines would be expected to be more difficult than making a distinction between either of them and, for example, the unrelated variety Cape (Table 1). Even more evident, of course, is the difference between any of these barleys and representatives of a distinct species or genus, e.g., wheat (genus *Triticum*) or maize (genus *Zea*: Table 1).

The practice of finally selecting a variety for registration often involves taking several plants from an advanced line many generations from the original cross. The combinations of genes in these lines are thus "fixed" (homozygous, of stable genotype), but they may differ from one another in subtle ways, although they are uniform in appearance as plants. Subsequent analysis of individual grains by sensitive methods of variety identification may provide a distinction between these component genotypes (termed "biotypes"), although all are authentic parts of the same variety. For example, gel electrophoresis of the grain proteins of the wheat Marquis (Table 1) has shown that there are distinct biotypes; one of these, Marquis K has been suggested as a standard sample for electrophoretic identification.

The term "cultivar" has been used to indicate a homogeneous population of plants of common pedigree which breeds true. The word is loosely used as being equivalent to the term "variety," but, in theory, "cultivar" refers mainly to plants having a single phenotype, whereas the term "variety" is slightly less restrictive. Nevertheless, common usage continues with the term "variety," and it is adopted throughout this article.

Recent years have seen a further breakthrough in breeding technologies, involving the use of genetic modification (GM) to introduce genes from species unrelated to the target genotype. An example is the maize variety, StarLink (Table 1). The need for "identity preservation" of GM varieties in some regions adds to the need for variety identification, so that such grain is received and transported separately from conventionally bred varieties. However, identity preservation is not restricted to GM varieties; it is a standard practice in many grain-producing countries to insure that grain of premium quality is not mixed with that of inferior or different quality type.

Plant Breeders' Rights Requirements

Another important reason for satisfactory methods of variety identification is the need to implement plant breeders' rights (*see* **Variety Registration and Breeders' Rights**), the system for breeding organizations to be remunerated financially for the use of their varieties, in a process similar to that of copyright laws. These systems require that a new variety must be registered, defining its identity, with evidence that it is distinct from other varieties of the respective species, that it is uniform with respect to relevant characteristics, and that it is stable for those characteristics from one generation to another. This process should also provide the means of identification, permitting this variety subsequently to be identified at the time of sale of seed or delivery of harvested grain.

However, it has become difficult to provide methods that are sufficiently discriminatory for this purpose, especially for closely related varieties (such as sister lines – Figure 1) without the need for excessive cost, labor input, or resources in expertise or equipment. Methods used for registration under PBR may not be readily deployable in "field" situations.

The range of methods devised for distinguishing between varieties of cereal grains differs according to their discriminating ability and the degree of difficulty in implementation.

Grain and Plant Morphology for Identification

Traditionally, distinction has involved visual inspection of plants or grain, probably aided by reference manuals listing systematic descriptions relevant to the species under examination (*see* **Grain and Plants, Morphology**). This approach satisfies the requirements of speed and minimal resources, but it is subjective and its capability for discrimination is generally poor. Visual examination can be implemented in any situation "on the spot," requiring no more than good lighting, and possibly a hand lens for magnifying small details. Experience is obviously essential, even when reference manuals are available, often involving a lifelong vocation.

The specific characteristics that provide distinction differ from one species of grain to another. Ideally, these distinguishing markers are genetically determined, without modification by variations in growth conditions. This ideal situation is often not possible. Nevertheless, such markers are available to a limited extent. For example, color differences are an obvious basis for distinction, such as blue aleurone coloration in barley grain, and red/white grain in wheat. Other useful characteristics are illustrated in Figures 2 and 3 for wheat plants. The auricles of a young wheat plant (3–6-leaf stage) may be either smooth or hairy, the auricle being the claw-like appendage that clasps the stem of the wheat plant at the base of the leaf (Figure 2). Genetic variation is also seen in the shape of the glumes – the outer husk that surrounds the grain in the mature wheat head (Figure 3). Particularly evident is the length of the "beak" (a spike projecting from the creased edge of the glume at the end of the glume opposite to the point of attachment to the rachis). This characteristic is especially useful since glumes are often found in grain samples, so that its value is not necessarily confined to plant identification.

In recent years, attempts have been made to obtain objective identification of varietal differences in morphological characteristics using image analysis, taking advantage of the speed and power of computing to analyze the image of grain profiles from a video camera. The technology appears to require further development for it to permit sufficient discrimination for routine variety identification, but image analysis is well suited to provide distinction between grains of different quality types or distinct species.

Established Laboratory Methods for Variety Identification

To overcome the subjective nature of visual examination, recourse has been made to a range of laboratory-based methods to achieve objective and definite identification.

The Phenol Test

A simple test, for example, for wheat varieties is the phenol test. This involves soaking grains in water for several hours, and spreading them on filter paper that

is wetted with a 1% solution of phenol in water. After a few hours at room temperature (20–25°C), there is color development (Figure 4) according to the genotype of the variety, shown as degrees of brown from colorless through to black. Generally, four degrees of coloration are distinguished – no change, light, medium, and dark – these are gaged by the inclusion of grains of known phenol reaction. The test thus does not have great discriminating power, but it has the advantages of low cost and ease of performance, especially for large numbers of grains. This latter advantage is considerable in relation to assessing statistical significance for a sample containing a mixture of varieties that differ in phenol reaction. The genes responsible for the phenol reaction have been mapped to specific chromosomes of wheat, namely, chromosomes 2A and 2D (*see* **Wheat**: Genetics), based on studies of the variety Chinese Spring. The phenol test can also be applied to the glumes of wheat as a further indication of variety, provided head samples are available, or if the grain sample contains husk material. The results of the phenol test are not affected by variations in the growing conditions of the wheat grain, except in the case of severe deficiency of copper, as the enzymes responsible for the phenol reaction require copper as a cofactor.

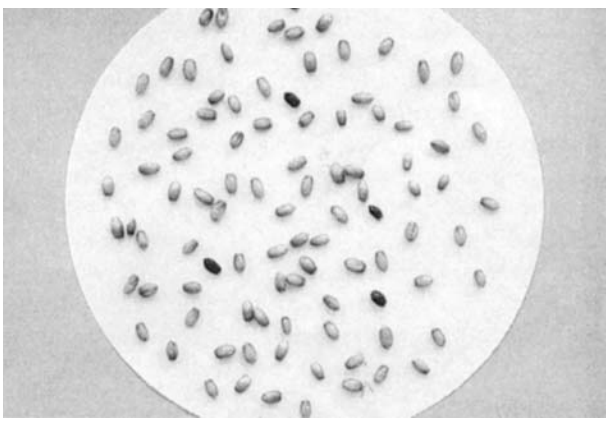

Figure 4 Color changes in wheat grains due to application of the phenol test. Most of the grains on the disk of filter paper have given a light-brown reaction. Grains of a different variety have turned dark brown.

Testing at the DNA and Protein Levels

The most commonly used laboratory tests for variety involve analysis at the gene (DNA) or protein levels. New technologies at the genome level offer the possibility of conducting varietal identification by DNA analysis efficiently and economically. Analysis at the genome level excludes the possibility of interference from fluctuations in the growth conditions, because it occurs at the start of the sequence of events shown in Figure 5. These events extend from the genes through protein synthesis to the formation of all components of the grain. This composition largely determines processing characteristics and final product quality.

The second major possibility for variety identification – the analysis of protein composition – provides the risk that the influence of growth environment may interfere with the attempt to identify genotype. However, analyses of the storage proteins of many cereal grains have demonstrated that the influence of growth conditions is not so great as to cause major difficulties in the interpretation of the results. Major advantages of choosing protein composition as the basis for study are that proteins are more abundant, compared to DNA, and that proteins are easier to extract for analysis by traditional methods. Several technologies of protein fractionation have been applied to variety identification. They differ in their complexity, cost (in capital and consumables), and distinguishing ability.

Gel Electrophoresis

Analysis of grain-protein composition by polyacrylamide gel electrophoresis (PAGE) has been accepted for some decades as the routine method of identifying cereal varieties in the laboratory. There are standard methods for the conduct of electrophoretic identification adopted by several scientific bodies, including the International Association for Cereal Science and Technology (ICC), the International Seed Testing

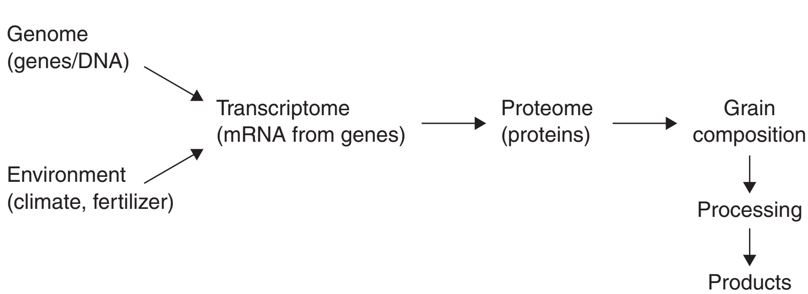

Figure 5 The sequence of events from genes, through protein synthesis to the final determination of product quality. Analysis of varietal identity is generally directed at the DNA or protein levels.

Association, and the Royal Australian Chemical Institute.

Extraction of grain proteins For electrophoretic identification, proteins are extracted from the milled grain (or a single crushed grain), using a solvent that selectively dissolves the relevant class of proteins (e.g., wheat gliadins). The proteins in solution are separated from the insoluble material by centrifugation. A small amount (a few microliters) of the protein solution is applied to the top of a slab of gel material, held between parallel plates, and under the electrolyte buffer that serves to conduct the electric current (DC) that is next applied (Figure 6). The protein molecules migrate into the gel according to the strength of attraction caused by their electric charge, with a retarding effect proportional to the size of the protein molecules.

At the end of the electrophoresis run, the gel material is removed and is stained to visualize the protein zones inside the gel. Figure 6 shows protein extract being loaded on to the top of a precast gel in the electrophoresis equipment. Figure 7 shows the results from one slab gel, on which several protein samples have been run in parallel. The result for each sample is represented by a series of horizontal lines ("bands") down the gel, each band representing a different protein. Some protein bands (in the same positions) are common to all the varieties (as shown in Figure 7), but there are other protein bands that are the basis of distinction between the varieties.

The gel medium In early versions of electrophoretic identification, a starch gel was used as the electrophoresis medium. This was subsequently changed to polyacrylamide gel, involving the polymerization of acrylamide (plus cross-linker) in the laboratory, but also using precast commercially available gels, provided ready to use, in disposable cassettes. The standard method of the Royal Australian Chemical Institute specifies the use of polyacrylamide gels in which the concentration of polyacrylamide increases from the top (where the sample is applied) to the bottom, thereby creating decreasing pore sizes to sort the proteins according to their size, and to cause sharpening of the protein zones as they pass through the gel medium under the attraction of the electric field.

Different gel ranges are specified for the various cereal grains, and also different extractants and run times, as tabulated in Table 2. These conditions are designed to provide electrophoretic profiles for the prolamin class of proteins from these cereal grains, known as gliadins for wheat, secalins for rye, and hordeins for barley. (*see* **Cereals**: Protein Chemistry. **Protein Chemistry of Dicotyledonous Grains** and **Wheat**: Grain Proteins and Flour Quality.) In the case of wheat, for example, the gliadins represent ~40% of the protein content of the grain. A further 40% consists of the glutenin proteins, which are not extracted under the conditions of Table 2, due to their large size.

SDS gel electrophoresis The polypeptides of wheat glutenin can be included in the electrophoretic profile by using an alternative system of extraction and electrophoresis. This involves the inclusion of a reducing agent to break disulfide bonds that hold the polypeptides of glutenin, together with the inclusion of the detergent sodium dodecyl sulfate (SDS) in both extraction and gel systems. In this way, many more protein zones may be displayed, thereby increasing the chances of showing differences in protein composition, and thus providing distinction between varieties.

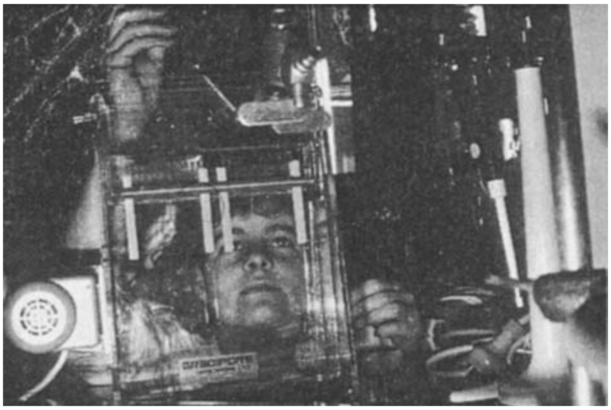

Figure 6 Electrophoresis equipment in use for variety identification. Grain-protein extract is being loaded on to the top of a precast gel, prior to switching on a voltage (direct current), which will attract the protein molecules down into the gel for separation into their various fractions.

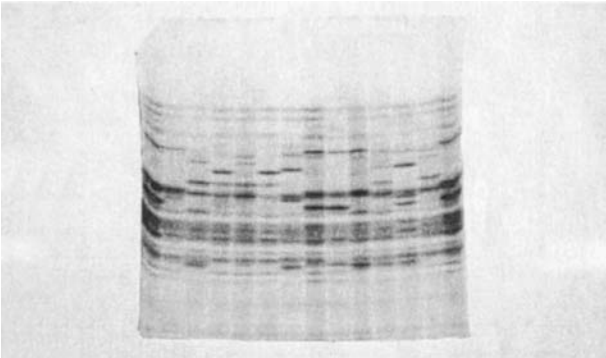

Figure 7 The gel patterns resulting from electrophoretic identification of a series of wheat varieties on the basis of their gliadin bands, separated by cathodic gel electrophoresis in a precast gel (3–15% polyacrylamide) at pH 3. The gel measures ~7 cm wide and 7 cm high, and is 1 mm thick.

Towards Better Methods for Variety Identification

The shortcomings of established methods of identification have prompted research into better laboratory-based methods, with the aims of providing good distinction and more efficient handling of samples. The following methods, recently developed, offer these advantages (Table 3).

Capillary Electrophoresis (CE) and Reversed-Phase High-Performance Liquid Chromatography (RP-HPLC)

CE and RP-HPLC offer alternatives to gel electrophoresis as a means of achieving efficient fractionation of the grain proteins for variety identification. The bases of fractionation by PAGE, by CE, and by RP-HPLC appear to differ from one another, so the use of any of the three holds promise of providing distinctions between varieties. Standard procedures have been developed for the use of CE and RP-HPLC, detailed in the "Official Testing Methods Handbook" of the Royal Australian Chemical Institute.

Figure 8, for example, shows CE profiles for gliadins from grain of wheat varieties. The respective gliadin proteins have been separated according to their charge properties during passage through a CE column. As the protein zones exit the column, they are detected by their absorption of ultraviolet light, so that the separate fractions appear as a series of peaks, the overall profile providing a "fingerprint" characteristic for the individual variety.

The system of detection is similar in the case of RP-HPLC, but the separation medium is different (a chromatography column is used) and fractionation is based on a different characteristic of the proteins, namely, their hydrophobicity, the respective protein components being retarded to varying degrees as they pass through the column.

Both CE and RP-HPLC are much faster than conventional gel electrophoresis. Rapid identification of wheat varieties is possible in less than 1 h using either CE or RP-HPLC to determine gliadin composition. Furthermore, automatic loading facilities permit analyses to proceed unattended, for example, overnight. They offer the additional advantage of providing the results as electronic data for automatic processing of the results. In this way, the profile of unknown sample can be matched against the stored profiles of authentic samples, allowing the best match to be obtained as the identity of the unknown sample.

Mass Spectrometry (MS)

Mass spectrometry is another alternative developed recently for rapid analysis of identity based on protein composition. The main demonstration of its capability is again based on the analysis of gliadin proteins

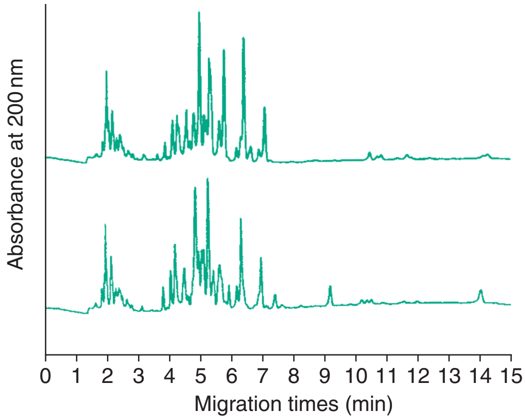

Figure 8 Capillary electrophoresis profiles for gliadin proteins, extracted from grain of wheat varieties Halberd (top) and Cranbrook. (Reproduced with permission from Wrigley CW and Bekes F (2002) Grain-protein composition as a document of wheat-quality type: new approaches to varietal identification. In: Ng PKW and Wrigley CW (eds.) *Wheat Quality Elucidation: The Bushuk Legacy*, pp. 65–86. St. Paul, MN: American Association of Cereal Chemists.)

from wheat grain. In this case, an accurate analysis is provided of the molecular mass of all the gliadin molecules, the resulting profiles being characteristic of the varieties analyzed. In these experiments, growth environment had little impact on the MS spectra. Analysis took only 2 min per sample manually, or 15 s per sample if automated. However, the equipment is expensive. The role for this approach to variety identification may in the future involve a central laboratory, with robotics for sample handling, and large numbers of samples to justify the high costs of the equipment. Nevertheless, the future also holds the prospect of smaller and cheaper MS equipment that may permit the more general use of this approach to variety identification.

Immunoassay

Aspects of protein composition can also be determined by using the specificity and speed of antibodies to indicate the presence (or absence) of proteins that are markers of specific varieties. The main possibility for this type of analysis is the use of a series of antibodies that would provide color reactions to indicate if the respective marker proteins are present in the extract of grain proteins. In practice, this system can be applied efficiently in the laboratory by using multi-well microtiter trays, with automatic multichannel pipettes and an automatic enzyme-linked immuno-sorbent assay reader. Alternatively, it may be adapted to on-the-spot identification with an extension of the immunochromatography test card, similar to that used in medical diagnostics.

Scenarios for Identification

These various methods of protein fractionation differ in their potential for distinction between varieties, and in their suitability for routine use, based on considerations such as speed, expertise required, and cost. For example, PAGE has the advantage of low cost for the equipment needed, compared to the much more expensive capital costs for the other alternatives described above. However, PAGE is labor-intensive, requiring a degree of skill, and it does not provide the possibility of immediate computer-based interpretation of the results. Relative suitability depends on the situation in which identification is needed. These situations are summarized in Table 4, namely:

- the need for rapid identification, when delivered grain must be assessed within a few minutes, with minimal facilities;
- the regional laboratory, with modest equipment and modest expertise, where questionable samples may be sent for a prompt result to be provided, possibly overnight; and
- a major centralized laboratory, with sophisticated equipment and trained staff, where the emphasis is on the efficient analysis of large numbers of samples. This third scenario suits the approach of having farmers' samples taken at the time of grain delivery, for subsequent analysis to verify the declaration of variety made at delivery.

Philosophy of Analysis

Clarification of the Aim of Identification

A proper appreciation of the aim of identification is needed in designing the best approach to the task, namely, "What is the question?"

- In general, the question to be addressed is one of verification of identity, that is, varietal identity has been specified for the grain sample to be analyzed, and testing requires a "yes/no" answer.
- The more difficult question follows from a "no" answer, namely, "What variety is it?"
- An intermediate possibility is the question "Is this sample variety A or variety B?"

The precision of the answers to any of these questions depends on the discriminating power of the test(s) applied. A reference list of varieties and their characteristics is essential to providing the information needed to make decisions about the type and degree of testing necessary to answer these questions. A test system that discriminates a large set of varieties into only two or three groups (e.g., the phenol test) cannot alone provide a precise answer to any of the

Table 4 The three major situations in which variety identification is needed and relative suitability of methods of identification

Examples of these situations	*Situations*		
	On-the-spot *Grain receival at mill or grain elevator (silo)*	*Regional lab* *Backup at mill* *Breeders' or seed lab* *Export terminal*	*Central lab* *Contract lab for large numbers of post harvest samples*

20	3–56	6–44	13–29	17–23
50	19–81	27–73	40–60	46–54

[a] Limits at 95% confidence level.

above questions. The strategy for efficiently answering the third question requires the results from testing the two varieties to be available, such as would be provided in a reference list. The adequacy of an answer to the second question depends on how comprehensive is the size of the catalog of test results, as well as the discrimination of the tests being applied.

Grain Sampling and Statistics

A basic requirement of satisfactory analysis of variety is that the sample taken for analysis is representative of the whole load of grain. This is relatively simple if it can be assumed that the load is uniform or homogeneous. Otherwise, the taking of a sample for analysis must follow a procedure designed to insure that the subsample reflects the composition of the whole consignment.

An additional consideration relates to interpreting the analysis of many individual grains. Obviously, the results for only one or a few individual grains do not indicate the identity of the whole load if it cannot be assumed to be uniform. Analysis of a milled sample provides a much better indication of identity if only one analysis is to be undertaken initially. In the case of a heterogeneous consignment, it may be necessary to perform grain-by-grain analysis – a tedious and expensive task – and the results must be interpreted for statistical significance.

Table 5 illustrates the problem. If analysis of 10 grains individually showed that they all had the same identity, it could not thus be assumed that the whole sample was uniform; the table shows that this result would indicate a 95% probability that there could be between 0% and 31% of a different variety present. These confidence limits become much narrower with the analysis of more grains. Likewise, if two grains (20%) in 10 were found to be of a different variety, the confidence limits for that different variety in the whole load would be 3–56%.

Future Prospects

Further developments already at the research stage promise better capabilities for the automatic analysis of large numbers of samples, using DNA or antibody probes, with microarray technologies. In this way, reactions to many such probes are determined simultaneously, thereby greatly increasing the possibility of obtaining distinctions. The remaining tedium of handling large numbers of samples is likely to be overcome by the use of robotics in a central laboratory where such expense would be justified.

VARIETY REGISTRATION AND BREEDERS' RIGHTS

R J Cooke, NIAB, Cambridge, UK
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

It is well known that there are different species of grain crops, with varying end uses. However, within each grain crop there also exists a large number of different types, which might be farmers' selections, landraces, or cultivated varieties (cultivars) actively produced by plant breeders. Such varieties may differ significantly in their genetic potential. These differences relate both to their agronomic potential (e.g., yield, maturity, or disease resistance) and to their suitability for end use, hence affecting the market value of the grain. Thus, for instance, varieties of wheat suitable for bread making may attract a premium in the marketplace, both nationally and internationally. Because there are these differences between varieties of any grain species, it is necessary to have a system of market regulation and consumer protection, usually achieved by naming and registering each variety. Furthermore, there must be a recognition that this range of beneficial characteristics has been "built in" by plant breeders, at considerable cost to the breeding organization.

Accordingly, most grain-growing countries have an official system for the registration of new varieties. In addition, it has been considered appropriate internationally that the efforts of the breeder should be rewarded by the payment of royalties on the seed of their varieties sold. These payments are thus generally paid by the farmer, as the primary beneficiary of the breeding effort. To establish such payment systems, legislation has been enacted in most grain-producing countries under the title of Plant Breeders' Rights (PBR) or Plant Variety Rights (PVR). These are intellectual property protection schemes, operating in a manner somewhat analogous to that of copyright or patenting systems.

Historical Background

When farming, as opposed to the hunter-gatherer life style, became established, the wise farmers set aside part of their crop as seed for the next season. This permitted early attempts to produce improved "varieties" to be undertaken, simply by the selection of superior plants from an otherwise varied crop. In turn, such selection permitted the separate propagation of parts of the crop that showed, for example, well-filled heads or resistance to pathogen attack. An example of this process is the selection of the malting barley Prior (released in Australia in about 1900) from the traditional English barley, Archer (**Variety Identification of Cereal Grains**). Individual farmers often practiced this approach, and, as they wished to improve their planting stock, they would pass on their improved variety to neighbors or sell the seed on a wider scale. This led, in turn, to the establishment of a trade in seed, both locally and, in time, internationally. It was usual for the selling agent to promote the seed for sale, using a name that was designed to enhance its attractiveness to the buyer. However, in these early days, there was little regard for the authenticity of these names. Systematic plant breeding by selection was established seriously by the end of the eighteenth century when the plants being grown by farmers were the result of several thousands of years of partly conscious, partly unconscious selection. However, the potential for improvement based solely on selection was very limited.

It was not until early in the twentieth century, with the rediscovery of Mendel's laws of heredity, that deliberate cross-pollination followed by selection contributed to the establishment of plant breeding on a much more scientific basis. The essence of plant breeding is the creation of genetic variation within a species and the subsequent selection from within that variation of plants with suitable combinations of desirable traits that can be inherited in a stable fashion. The plant breeder's final selections of superior plants will form the basis of one or more plant varieties. The introduction of cross-pollination greatly increased the genetic diversity from which to select improved lines or genotypes. This mechanism is illustrated (**Variety Identification of Cereal Grains**) by the production of the Australian malting barleys, Clipper and Cutter, released, respectively, in 1968 and 1975. These are "sister lines," being separate selections from the same cross, involving an old English variety Proctor (bred in 1952) and Prior A, a line arising from the cross between the varieties Kwan and Prior.

The breakthrough of cross-pollination a century ago also moved the scene for producing better varieties from the individual farmer or interested amateur to organized science – either government sponsored or in private industry. The success of a breeder depends, to

a large extent, on the number of potential new varieties that can be screened within a breeding program, and on the ability to identify the traits of interest. Scale is thus very important and plant breeders will use all available technologies, both to create genetic variation and to select from within that variation. Recent years have seen breakthroughs in breeding technologies, involving the use of genetic markers, which permit the selection and identification of desirable traits at the DNA level, reducing both time and costs. Furthermore, genetic modification (GM) is now possible, permitting the introduction of genes from species unrelated to the target genotype, much more rapidly than conventional techniques.

It is thus clear that the breeding of a plant variety takes place over many years, and requires significant investment, for example, in land, specialized equipment, and skilled scientific manpower. Not all breeders or all varieties are successful and, even where successful, changes in market requirements may reduce the returns on investment. However, there is undoubtedly a benefit to society and to countries in the continued production of new and improved varieties, not least in terms of securing the food supply. Hence, it has been generally recognized that there are good reasons to encourage investment and risk taking in this field, and one way of encouraging such investment is through variety registration and PBR schemes.

PBR – Background and the Role of UPOV

PBR schemes are a mechanism for intellectual property protection, applicable to newly developed varieties of all agricultural and horticultural species, including all of the major grain crops. PBR systems are attracting an increased interest and significance worldwide due to developments within the World Trade Organization (WTO). As part of being a signatory to the WTO, countries agree to abide by the conditions of trade related intellectual property systems (TRIPSs), and a condition of TRIPS is that an "effective system" for the protection of new plant varieties exists. WTO members are thus establishing (or have already established) systems for PBR. Most of them are adopting PBR based on the principles of the International Union for the Protection of New Varieties of Plants (known as UPOV, from the French acronym – see www.upov.int for more information).

UPOV has its headquarters in Geneva and has over 50 members. One of the primary functions of UPOV is to coordinate the legal and technical aspects of PBR systems worldwide, and to this end, there is a UPOV Convention (latest version 1991), setting out the principles for PBR. The cornerstone of the UPOV PBR system is that in order to qualify for protection, a newly bred plant variety has to be shown to be new, distinct from others "of common knowledge" and sufficiently uniform and stable in the characteristics used to demonstrate distinctness. An important activity of UPOV is to produce guidelines for conducting this distinctness (D), uniformity (U), and stability (S) testing in a wide range of crops – there are now UPOV guidelines for more than 250 different species, with others in development. The guidelines contain lists of characteristics that can be used for distinctness, uniformity, and stability (DUS) testing of a given species, as well as instructions for how to record these characteristics and "example varieties" which demonstrate the various states (or "UPOV notes") of a characteristic (see Table 1 – extract from current wheat guideline). The characteristics currently used for DUS testing are almost exclusively morphological features of the seed, seedling, or developing plant. For instance, in barley there are 29 characteristics in the current UPOV guideline, whereas in wheat there are 26 in total. These include features such as plant length, growth habit, time of ear emergence, color of ears, and width of straw. While some of these are clearly measurable in absolute terms (e.g., length), others exist in only a few discrete states (ears are either white or colored) and others again are relative (frequency of plants with recurved flag leaves – absent/very low to high). In most cases in grain crops, the characteristics are recorded on a 1–9 scale (e.g., plant length is recorded as very short (note 1) to very long (note 9)). In addition, countries can use extra characteristics, which they have found to be useful for DUS purposes in their own environments. It must be remembered that the guidelines are not mandatory – they are lists of characteristics that have been shown to be useful for distinctness testing and variety description. Some of the characteristics are asterisked, to indicate that they should always be recorded and included in the variety description (see Table 2).

In principle, DUS testing requires that each new (or candidate) variety received for PBR is grown in replicated plots and all of the UPOV characteristics (plus any agreed additional ones) are recorded at the appropriate growing stage. These data are used to compile a description of the candidate variety, which is then compared with the descriptions of all of the varieties in a reference collection. This comparison is in theory made with all varieties of common knowledge. However, in practice this is not really possible, and most testing authorities only make comparisons with a "working reference collection," which might typically consist of current varieties grown in a particular

Table 1 Extract from UPOV guideline for wheat DUS testing

	Characteristics Caractères Merkmale	*Stage Stade Stadium*	*English*	*Francais*	*Deutsch*	*Example varieties Exemples Beispielssorten*
1.	Coleptile: anthocyanin coloration	09–11 VS	absent or very weak	nulle ou trés faible	fehlend oder sehr gering	Herzog; Delos
			weak	faible	gering	Niklas; Baldus
	Coléoptile: pigmentation anthocyanique		medium	moyenne	mittel	Andros; Planet
			strong	forte	stark	Obelisk; Briscard
	Keimscheide: Anthocyanfärbung		very strong	trés forte	sehr stark	Albatros; -
2.	Plant: growth habit	25–29 VG	erect	dressé	aufrecht	Castan; -
			semi-erect	demi-dressé	halbaufrecht	Frandoc; Remus
	Plante: port au tallage		intermediate	demi-dressé à demi-étalé	mittel	Obelisk; Troll
			semi-prostrate	demi-etalé	halbliegend	Boss; -
	Pfalanze: Wuchsform		prostrate	étalé	liegend	Beaver; -
3.	Flag leaf: anthocyanin coloration of auricles	49–51 VG	absent or very weak	nulle ou trés faible	fehlend oder sehr gering	Soissons; Prinqual
			weak	faible	gering	Niklas; Troll
	Dernière feuille: pigmentation anthocyanique des oreillettes		medium	moyenne	mittel	Cardigoc; -
			strong	forte	stark	Cargo; Sunnan
	Oberstes Blatt: Anthocyanfärbung der Auricula		very strong	trés forte	sehr stark	Recital; Dollar
4.	Plant: frequency of plants with recurved flag leaves	47–51 VG	absent or very low	nulle ou trés faible	fehlend oder sehr gering	Apollo
			low	faible	gering	Recital; Axona
	Plante: fréquence de plantes avec la dernière feuille retombante		medium	moyenne	mittel	Obelisk; Filou
			high	forte	stark	Frandoc; Prinqual
	Pflanze: Häufigkeit van Planzen mit gebogenen obersten Blattern		very high	trés forte	sehr stark	Capitole; -

country or region along with others that are available commercially or are of interest for other reasons (e.g., they display a range of expression of the UPOV characteristics). If the new variety is found to be D and sufficiently U and S on the basis of this examination, it can be granted PBR, and the description produced then legally defines the variety, along with an acceptable variety name (or denomination). It is important to note that UPOV does not prescribe how the DUS examination is carried out, and there are many different approaches to the award of PBR that have been adopted by UPOV members (see below).

Table 2 Example of a variety description

Char. no.		Character	State
UPOV	UK		
01	01	Coleoptile – anthocyanin coloration*	Medium to strong
02	02	Plant – growth habit	Intermediate
04	06	Plant – freq. of plants with recurved flag leaves	Absent
05	08	Time of ear emergence* (first spkt visible – 50% ears)	Late
03	09	Flag leaf – anthocyanin coloration of auricles	Absent/very weak
06	14	Flag leaf – glaucosity of sheath*	Very strong
08	16	Culm – glaucosity of neck	Very strong
07	17	Ear – glaucosity*	Very strong
09	21	Plant – length (stem, ears, awns, and scurs)*	Short to medium
10	22	Straw – pith in cross-section*	Thin
16	25	Ear – color*	White
14	26	Awns or scurs – presence*	Scurs present
15	28	Awns or scurs at tip of ear – length*	Very short to short
11	30	Ear – shape in profile*	Tapering
13	31	Ear – length (excluding awns or scurs)	Medium
12	33	Ear density*	Dense
20	41	Lower glume – beak length	Long
21	42	Lower glume – beak shape	Slight/moderately curved
18	45	Lower glume – shoulder width	Medium
19	46	Lower glume – shoulder shape	Elevated with 2nd point
22	52	Lower glume – extent of internal hairs	Group 1+ to 2 (Jonard 1–2)
23	55	Lowest lemma – beak shape	Strongly curved
17	68	Apical rachis segment – hairiness convex surface	Weak to medium
24	69	Grain – color*	Red
25	79	Grain – coloration with phenol	Medium
26	80	Seasonal type	Winter type
27	81	SDS-PAGE electrophoresis – glutenin locus Glu-A1	No band
28	82	SDS-PAGE electrophoresis – glutenin locus Glu-B1	Bands 6 + 8
29	83	SDS-PAGE electrophoresis – glutenin locus Glu-D1	Bands 2 + 12

As an intellectual property protection system, PBR schemes have to be adopted into the national legislation of countries. The UPOV Convention sets out the scope of the protection, including the requirement that the holder's prior authorization is necessary for commercial production, marketing, sale, and marketing of propagating material of a protected variety. The breeder's right extends not only to the protected variety itself but also to varieties whose production requires the repeated use of the variety (e.g., F1 hybrids), and – in the 1991 Convention – to varieties that are "essentially derived" from the protected variety. This is a mechanism designed to cope with the GM of existing varieties, e.g., by the insertion of a single new gene, but also encompasses other aspects of so-called cosmetic breeding. Under PBR systems, protection is granted for a limited time, after which varieties pass into the public domain. In contrast to patents, PBR extends only to the actual variety (as defined in the Convention) and not to any single trait or characteristic of a variety in isolation. Moreover, authorization of the holder of the right is not required for the use of a protected variety for "research" purposes, including the breeding of new varieties. The Convention also allows for a farmer's subsequent use of harvested seed of protected varieties, under national legislation.

It is important to note that DUS testing does not examine the merit or value of new varieties, and the characteristics used do not usually have any particular agronomic significance. This is primarily because of the requirement to compile a description of the variety, which becomes the "definition" of the variety and has to be maintained while PBR is in force. Performance characters such as yield or quality are not reliable indicators of identity, as they are subject to environmental interactions and are thus difficult to describe with sufficient precision. Uniformity and stability assessments of such characteristics would also be difficult to undertake. In many countries, the question of agronomic value is assessed in a different process, usually known as variety registration.

Variety Registration and PBR Schemes in the European Union

The member states of the European Union (EU) operate a very comprehensive system of DUS testing and PBR of agricultural crops. This arises from the

existence of a Seeds Directive (72/180/EEC), which requires that before a new variety can be marketed, it has to be included on the "national list (NL)" of a member state, or on the "common catalog" (essentially a compilation of NLs). To be included on an NL, a new variety has to be shown to be D, U, and S, and also to have sufficient value for cultivation and use (known as VCU). The VCU of a variety is satisfactory if "... its qualities ... offer a clear improvement ... ." This improvement must be in "cultivation, or as regards the uses which can be made of the crops or the products derived therefrom," and the qualities of varieties are "... taken as a whole ... ." The DUS criteria are also used for awarding PBR, at the breeder's request. 72/180/EEC also specifies the way in which the DUS and VCU testing are to be carried out. In general, breeders submit their varieties to a national testing PVR office, and a series of "official" trials and tests are required, usually over a 2 year period, using prescribed protocols. Following compilation and collation of the data, including statistical scrutiny/analysis if appropriate, decisions on the DUS and VCU status of candidate varieties are made by a national board or committee. There are certain differences between member states as to who actually carries out the NL testing. In some countries (e.g., Germany), the testing is all carried out by government scientists, whereas in the UK, much of the technical work is subcontracted to private organizations, with the administration of the system carried out by government departments. Generally though, all EU member states conduct DUS tests for the award of PBR, based on the principles and methods of the UPOV guidelines. A complete variety description is produced (e.g., Table 2) and evidence of the distinctness of the variety from its most similar existing variety is required. A sample of the seed of the variety must be kept by the testing office, as the official reference sample.

In addition, there exists the Community Plant Variety Office (CPVO), a supra-national organization that grants protection to breeders in the form of EU-wide PBR. The CPVO does not conduct any tests or trials for itself, but subcontracts the technical work to EU member states. At the moment, the majority of CPVO applications are for ornamental species, with breeders of the major grain crops still on the whole opting for national protection, primarily because of the VCU requirement.

Some countries within the EU operate schemes for the collection of royalties payable to plant breeders on the farm-saved seed of registered and protected varieties. This follows the introduction, in 1994, of EC regulations, allowing plant breeders "... to collect remuneration that was 'sensibly lower' than the certified seed royalty rate, for protected seed that was produced and then saved by the farmer and used on his own farm ... ." For example, in the UK the British Society of Plant Breeders (BSPB) has the legislative authority to collect this remuneration on the farm-saved seed of certain protected varieties that had been granted European and/or UK rights after 1994. This applies to varieties of cereals, field peas and beans, oilseed rape, linseed, and triticale. There is only one remuneration rate for farm-saved seed per species, but each variety has its own individual royalty rate for certified seed. Such payments represent an important source of income for breeders, and additional return on their original investments.

Although it may appear unduly complex to have variety testing being conducted in 15 different countries for the same purpose, in practice the system has worked well and has delivered a series of improved, high-quality varieties to European farmers since the early 1960s. In turn, these varieties have enabled grain production in Europe to increase, without a major rise in the land under cultivation (i.e., efficiency and productivity have increased). The effects of enlargement of the EU, and the increasing number of countries in the UPOV system, along with the need to contain the costs of the system, may change this situation in the future (see below).

PBR Schemes in North America

By contrast to the situation in the EU, PBR systems in the USA have no official trials system. In addition, various different types of protection are available to US plant breeders. The Plant Variety Protection Act (PVPA) provides for PBR under the UPOV system (the USA is a member of UPOV), although there are no trials and no inspection of new varieties. Rather, breeders submit a description of their variety, using UPOV guidelines where appropriate, and a comparison of this description and those of other varieties of the species in question is made by the PVPA office, using a database of existing descriptions. However, no sample of the new variety is required or kept by the office. The Plant Patent Act (PPA) is limited only to asexually reproducing species and hence excludes the major grain crops. However, utility patents are available for inventors (breeders) of new varieties, a decision which has been confirmed recently by a decision in the Supreme Court (*J.E.M AG Supply Inc v. Pioneer Hi-Bred International Inc*, 2001). The subject matter for such patents is defined in Section 1010 of title 35 of the US Code. They require a demonstration of novelty, nonobviousness, and utility, and the applicant also has to fulfill the other requirements of US Patent Law, such as the need

for a substantive description – requirements which are arguably more stringent than those required under UPOV-type PBR systems. A deposit of seed of the variety is also required, which becomes publicly available. In return, the protection offered by a utility patent is more restrictive than a more traditional PBR award. For example, the variety cannot be used for breeding without the consent of the patent holder, as this would represent product development under patent law.

Canada has had a PVPA since 1990 and operates a breeder testing system, in accordance with UPOV principles. Although there are no independent official trials, applicants are required to grow their new varieties in comparison to closely similar types, and these trials can be inspected by government officials. The results of the descriptions of new varieties submitted by breeders can also be checked in the field by officials, or their advisors. Breeders have to supply an official sample of newly registered varieties, which is kept in a gene bank. Primary registration required by the Canadian Grain Act involves consideration of functional quality and kernel visual distinguishability. However, the latter requirement is in the process of change, with an added emphasis on distinguishability according to laboratory methods of identification.

PBR Schemes in Other Countries

There are many other countries with PBR systems, and a range of options for operating these systems has been followed. New Zealand and South Africa have systems in place which are broadly along the lines of the Canadian model (i.e., breeder based), but can require more substantial tests, including the possibility of official tests if these are deemed necessary by the authorities and the production of a variety description by the officials rather than by the applicant. Japan has a range of systems in place, depending on the species – rice, for instance, is tested in an official series of tests by the National Center for Seeds and Seedlings, and/or by local government research institutes. Officials establish the final DUS report and prepare the variety description. There is also a VCU system for major crops, including rice and the other grain species. In Australia, a breeder-based system operates, and the applicant has to demonstrate that a new variety is D, U, and S, by carrying out comparative trials, supervised by the examination office. The variety descriptions (produced by the applicants, but checked by officials) are published, allowing for a period of public consultation and consideration before PBR is awarded. Royalties are collected for protected cereal varieties when the grain is delivered after harvest, as distinct from other systems, in which royalties are payable when the seed is sold.

Of the many countries that have established PBR systems since the advent of the WTO agreements, most seem likely to choose a primarily breeder-based approach, largely for cost considerations. Clearly though, there is considerable scope, even under the UPOV system, as to how DUS testing is conducted. Other countries such as India, although signatories to WTO, have yet to decide the details of their systems. The relevant act establishing PBR has passed through the Indian Parliament, but India is not yet a member of UPOV and may indeed never be. The principles of DUS testing are well established in the country, and India may decide to develop a "sui generis" system.

Advantages and Difficulties with Present PBR Systems

PBR schemes are now becoming very widespread, and the advantages that they bring to countries in terms of rewarding plant breeding effort and increasing the supply of high-quality varieties to the marketplace seem well established. For example, Brazil has reported that since the advent of PBR (1997), there have been increases in the number of varieties released, in the range of crops being bred, in private investment in breeding, and in productivity. It has been established that in the UK, PBR has expanded the genetic diversity of the major grain crops being grown, primarily by increasing the number of independent breeding companies releasing these varieties. However, there are some difficulties with the current PBR systems, both philosophical and technical.

For instance, the concept of the "ownership" of plant genetic resources is one which raises fundamental issues in some minds and fears that multinational seed companies might obtain a monopoly over food supply. It is also argued by some that the intellectual property protection systems that operate successfully in industrialized countries might not be suitable models for developing countries where agriculture is still a high-volume occupation. Again, the existence of PBR and "owned" germplasm might inhibit public-sector breeding, which is still very important in large areas of the world, and stifle investment in minor crops.

On the technical side, the expanding membership of UPOV and the number of countries operating PBR has a profound effect on the size of the reference collections that are used to make comparisons of new varieties with those of common knowledge. It is now impossible for any one country truly to compare new varieties with all those known to exist, especially

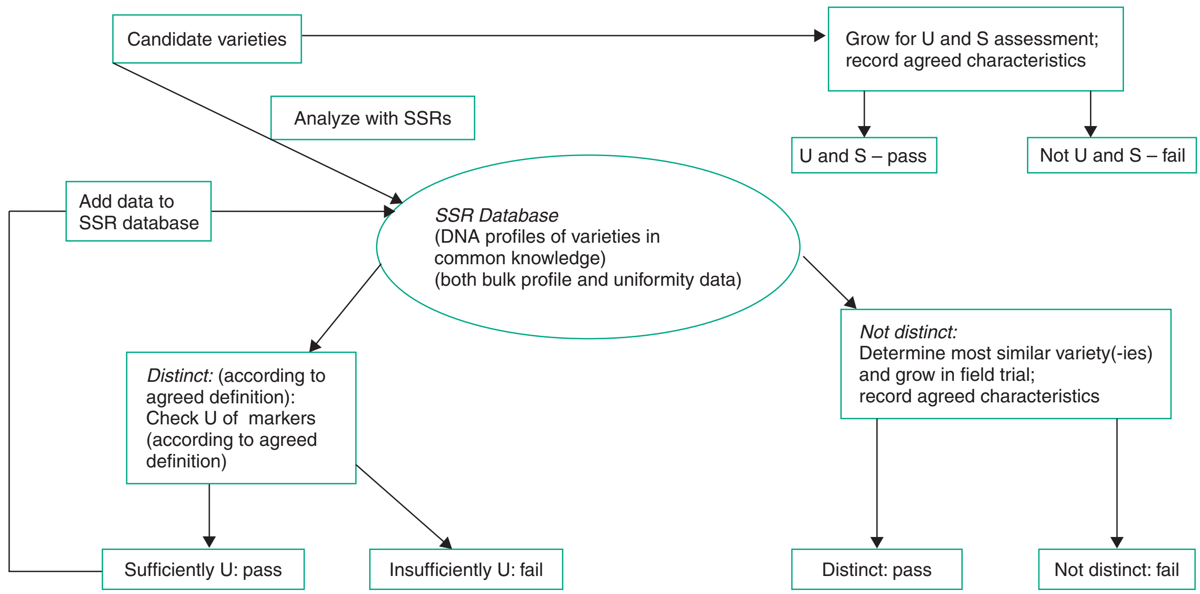

Figure 1 Possible future model for DNA-based DUS testing.

in the major grain crops. UPOV is also being forced to examine the concept and usefulness of the example varieties given in the guidelines (see Table 1), which now need to be available and to express the appropriate characteristic state on a worldwide basis. It is likely that regional example varieties and/or the use of digital photographs will be used in the future. For these reasons and also to constrain costs, new approaches to DUS testing utilizing modern technology are being seriously examined.

Future Prospects

The primarily UPOV-based PBR systems have served plant breeding and agriculture more generally, very well since the early 1950s. They provide effective protection, without imposing too much cost on either breeders or the responsible testing authorities. However, science does not stand still, and the advent of molecular markers and their use in breeding, along with the expansion of UPOV, offer new opportunities to devise more cost-effective, rapid, objective DUS systems and increase the quality and scope of protection of PBR. UPOV is taking this issue seriously, and has established a Biochemical and Molecular Techniques Group (BMT) as a forum to bring together scientists, breeders, and variety testers to discuss how best to make progress. One possible scheme for using DNA microsatellites (simple sequence repeats (SSRs)) in DUS testing is illustrated in Figure 1. Other possibilities also exist, but the fundamental point is to retain at least some aspects of morphology in testing, using molecular markers to reduce the number of comparisons that need to be made in the field and to make the publication of harmonized variety descriptions more possible and more useful. The same molecular description of a variety will be obtained wherever the analysis is carried out, which clearly is not necessarily the case for multigenic, complex, continuous morphological characteristics. In the longer term, as more becomes known about the molecular basis of genes and gene function, it is conceivable that PBR systems could be based more on the assessment of the functional diversity of varieties, including quality, disease resistance, and even yield, with these characteristics predicted from laboratory analyses rather than field trials. Thus, there is the prospect that a quantum shift occurs in the way that PBR schemes are operated around the world.

Genetics

R A McIntosh, The University of Sydney, Camden, NSW, Australia

Introduction

Common or bread wheat (*Triticum aestivum* L.) is an allohexaploid with 21 pairs ($2n = 42$) of chromosomes comprising three similar genomes (AA, BB, and DD) each of seven pairs. The species does not occur as a wild form; it evolved in agriculture ~9000 years ago. Durum or macaroni wheat and related cultivated and wild emmers (*T. turgidum* L.) are allotetraploids ($2n = 28$) possessing genomes, AA and BB, in common with hexaploid wheat. Einkorn (*T. monococcum* L.) is a diploid ($2n = 14$) that shares genome AA with both polyploid species. Within this species, there are both cultivated and wild forms.

Common wheat products are major components of food for about one-half of the world's population. This significance in agriculture has driven detailed study of the genetics of wheat and its relatives, a number of which have contributed genes for wheat improvement. A secondary, but important, reason for studying wheat genetics is that it is the best-understood genetic model of polyploidy, and study of the species has contributed to knowledge on chromosome pairing and to an understanding of how highly duplicated plant genomes are orchestrated to function within a single organism.

Common wheat has often been described as "soft" wheat to contrast it with the "hard" durum and emmer types. However, within common wheat, there is a bimodal distribution of grain textures also described as "hard" and "soft." The main gene controlling softness is located in the D genome so the trait does not occur in the tetraploid and diploid wheat groups.

Taxonomy of Wheat and Its Relatives

The allocation of wheat taxa to species and subspecies has changed periodically. The nomenclature of van Slageren is currently the most widely accepted. Although the closely related genus *Aegilops* shares the D and B genomes with wheat, *Triticum* and *Aegilops* have been treated as separate genera.

The Genomic Structure of Wheat

Common wheat has the genome groups AABBDD, durum and emmer, AABB, and einkorn, AA. The tetraploid cultivated form of *T. timopheevii* (Zhuk.) Zhuk. (AAGG) and hexaploid *T. zhukovsky* Men. & Er. are relatively unimportant. However, the wild AAGG form of *T. timopheevii* (ssp. *Ameniacum* (Jukubz.) van Slageren) may be more widespread than wild emmer which is largely restricted to Israel, Jordan, and nearby areas. It is agreed that the A genome of common wheat is derived from a close relative of *T. monococcum* known as *T. urartu* Tum. ex Gand. There has been an ongoing controversy regarding the diploid source of the B genome, but the current consensus of opinion is that it was *Aegilops speltoides* Tausch or a close relative within the Sitopsis section of the *Aegilops* genus. The D genome came from *Ae. squarrosa* Coss. A number of *Aegilops* species also possess a D genome and therefore hybrids with them show a degree of chromosome pairing and occasionally, a low level of fertility, which can be exploited in wheat improvement. Among the relatives of wheat, there are a number with distinct genomes that have functional, but not chromosomal, homology with those of wheat.

The Cytogenetic Structure of Wheat

Cytologically, common wheat behaves as a diploid species. At meiotic metaphase I, the chromosomes form 21 bivalents that regularly disjoin to produce gametes with $n=21$. This diploid-like behavior is genetically enforced, but mutants (*ph* mutants) that disrupt regular chromosome pairing have been isolated. Meiosis in these mutants is more typical of autopolyploidy permitting chromosome pairing between related or homeologous chromosomes.

Wheat Aneuploidy and Breeding Behavior of Monosomics

Despite regular chromosome pairing, chromosomes of all species occasionally fail to pair. Unpaired chromosomes behave abnormally in meiosis, resulting in gametes with missing or additional chromosomes. In most diploid animal and plant species, the zygotes (aneuploids) formed from such gametes are lethal or sublethal. In wheat, however, with its genomic triplication, aneuploidy in the form of either chromosome loss or addition can be tolerated. Between 1930 and 1970, several different series of aneuploids were isolated in common wheat cultivar (cv.) Chinese Spring by E. R. Sears at the University of Missouri. These lines formed the basis of modern wheat genetics and some of them continue to have a role in the current era of molecular genetics. Some of the more common wheat aneuploids are described in Table 1.

Table 1 Some aneuploid sets of Chinese Spring wheat

Aneuploid name	*Chromosome no.*	*Meiotic pairing (metaphase 1)*
Monosomic	41	$20'' + 1'$
Nullisomic	40	$20''$
Trisomic	43	$20'' + 1'''$
Tetrasomic	44	$20'' + 1''''$
Ditelosomic	40 + 2 telocentrics	$20'' + tt''$
Double ditelosomic	40 + 4 telocentrics	$20'' + tt'' + tt''$
Nullisomic–tetrasomic	42	$20'' - (1'') + 1''''$

$'$ = univalent, $''$ = bivalent, $'''$ = trivalent, $''''$ = tetravalent or quadrivalent.

When a monosomic wheat plant undergoes meiosis, the 20 bivalents separate in the normal reductional manner, whereas the unpaired univalent may reach one of the dyads, may divide mitotically in first division with the products reaching each dyad, or may lag to be excluded from both nuclei. At second meiotic division, the undivided chromosome, when present, divides normally with the other chromosomes, but if already divided, it may lag to be excluded from the nuclei of the resulting tetrads. The outcome of the various events over all monosomic chromosomes is that ~25% of resulting gametes have $n = 21$ and ~75% have $n - 1 = 20$.

On selfing or crossing to a monosomic as female, this is the realized proportion of functioning eggs. However, through the pollen, the gametes with $n = 21$ have a competitive advantage and contribute to pollination ~96% of the time (Figure 1). The results of self-pollination are that ~24% of zygotes are normal euploids, 73% monosomic, and 3% nullisomic. Individuals nullisomic for most chromosomes are morphologically weaker than monosomic and disomic sibs, and often sterile or partially sterile.

Gene Location by Monosomic Analysis

The unique breeding behavior of wheat monosomics allows dominant genes to be located to particular chromosomes. If Chinese Spring carries a dominant or co-dominant allele conferring a particular phenotype, that phenotype will be missing in the nullisomic for the chromosome that carries the gene (Figure 1). Another way to locate the same dominant gene (*AA*) in Chinese Spring is to cross the monosomics as female parents with a cultivar or line that carries

Female Transmission	Male transmission: 21 chromosomes 96% (81–99) $\boxed{A}$	Male transmission: 20 chromosomes 4% (1–19) $\boxed{-}$
21 chromosomes 25% (14–39) $\boxed{A}$	Disomic 25% (11–39) $\boxed{AA}$	Monosomic 1% (0.1–7) $\boxed{A-}$

Figure 1 The breeding behavior of a typical monosomic plant in Chinese Spring wheat with gene *A* located in the monosome. The percentage frequencies are mean realized values (and ranges). Frequencies in hybrid generations and other cultivars may exceed these values. For zygotic genotypes (boxes), the allele from the female gamete is written first.

the contrasting recessive allele (*aa*). In the "critical" cross, the monosomic individuals ($-a$) will have the recessive phenotype whereas in all 20 other crosses the monosomic hybrids will have the dominant phenotype (*Aa*).

The more usual situation is that the dominant gene is present in the nonmonosomic parent. In this case, hybrids can be generated, as above, to produce 20 sets of monosomics *aA* (female gamete written first) and a critical cross with $-A$; all have the dominant phenotype *A*. On self-pollination, the *Aa* individuals segregate normally, 3 *A* (1 *AA* + 2 *Aa*): 1 *aa* phenotypes, whereas in the critical line most of the plants (disomics + monosomics, see Figure 1) will have the *A* phenotype and a few may show the *aa* phenotype, but are actually nullisomic ($-$) and often characteristically weaker. Rather than demonstrate a cytological association between chromosome number and phenotype, researchers often have used a significant statistical deviation from the hypothesized segregation ratio to reach conclusions regarding gene location. Sometimes this led to failure of location, or incorrect location, due to incorrect hypotheses or to instances where nullisomic frequencies were higher than expected with the consequence that statistical deviations were not detected. Thus, the statistical test should be a guide to chromosome location and the prediction should be validated by chromosome counts or by further genetic tests.

The location of genes by monosomic F2 analysis was largely restricted to instances of single dominant gene inheritance, however other breeding strategies and appropriate cytogenetical models were designed to locate genes involved in more complex inheritance patterns. For traits controlled by two or more genes and for quantitatively inherited traits, the method of chromosome substitution was more appropriate. Chromosome substitution involves the production of a series of backcross-derived lines whereby monosomy is used to maintain the integrity of one chromosome of a donor parent while the remaining 20 chromosomes are converted to the genotype of the recipient parent by repeated backcrossing to the relevant monosomic line. After the last backcross (usually 6–10), a monosomic plant is self-pollinated, and a disomic is selected as the fixed substitution line. The 21 substitution lines thus generated can be assessed for the traits of interest and significant deviations from the phenotype of the recurrent parent are attributed to genes on the substituted chromosome originating from the donor parent. A large number of genes were located by monosomic and chromosome substitution methods.

Telocentric Chromosomes

During meiosis, unpaired chromosomes occasionally undergo misdivision, breaking at or near the centromere to produce either telocentric or isochromosomes. Most, but not all, monotelosomic (potentially 42) and ditelosomic plants in wheat are sufficiently normal and fertile to be maintained as distinct genetic stocks. Because telocentric chromosomes can be identified cytologically, they have special uses in gene localization to chromosome arms, in checking the identities of monosomic chromosomes by testcrossing, and for within chromosome recombination and mapping. Telocentric mapping exploits the use of the telosome as a centromere marker. Analysis of the progeny of a monotelodisomic ($20'' + 1t''$) heterozygote (*Aa*) allows determination of the genetic distance between a gene and the centromere (telocentric mapping, Figure 2).

In instances where a particular ditelocentric stock cannot be maintained due to sterility, a source of the telosome can be maintained either as a double ditelosomic stock ($20'' + tt'' + tt''$) or as a monoteloditelosomic stock ($20'' + tt'' + t'$). For example, an individual with 2BS, and not 2BL, can be generated using a CS DT2BS MT2BL ($20'' + tt_{SS}'' + t_L'$) as a female parent.

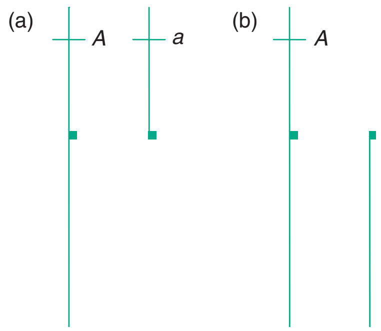

Figure 2 Method of telocentric mapping: When a plant of genotype *AA* is crossed to the alternative ditelocentric lines for the relevant chromosome, pairing can be as shown in (a) or (b). Genetic recombination in testcrossed or self-pollinated progenies of (a) can be estimated from the proportions of individuals with the contrasting phenotypes conferred by the *A/a* locus, and chromosome types. Genetic recombination for *A/a* and the centromere is not possible in (b); in this case, all progeny with phenotype *A* have an entire chromosome.

Nullisomic–Tetrasomic Lines

A very significant discovery by Sears was the realization that nullisomy for one chromosome can be compensated by trisomy or tetrasomy of the related or homeologous chromosomes from the other two genomes. The compensating combinations permitted identification of the seven sets of three homeologs numbered 1 to 7. Nonhomeologous nullisomic–tetrasomic combinations fail to show complementation and are phenotypically similar to nullisomics. Nullisomic–tetrasomic lines, in conjunction with ditelocentrics were essential in determining chromosome locations of the restriction fragment length polymorphism (RFLP) and microsatellite markers used to develop the skeletal chromosome maps of wheat. Most nullisomic–tetrasomic stocks are acceptably stable and fertile, but chromosome numbers should be confirmed in cycles of seed regeneration. The most significant exceptions are the nullisomic 4B combinations, which are sterile due to the absence of an essential gene for male fertility.

Although wheat chromosomes are comparatively large, they cannot be identified in general chromosome staining. As for many other species, however, they can be stained by C-banding procedures to produce unique banding patterns that enable the individual chromosomes to be identified by skilled technicians. C-banding was essential to the isolation and identification of a large number of deletion stocks that are enabling the physical mapping of many genes in wheat.

Aneuploidy in Tetraploid Wheat

Tetraploid wheat is much less tolerant of chromosome loss than common wheat, and monosomics are very difficult to maintain. The most stable and useful aneuploids developed for cytogenetic analysis at the tetraploid level were the durum cv. Langdon nullisomic-D genome substitution series produced in North Dakota. In these lines, the individual A and B genome chromosomes (except 4B) were replaced by D genome homeologues of common wheat cv. Chinese Spring ($2n = 28 = 14''$). When such plants are crossed with euploid durum the chromosome pairing in the hybrid is $13'' + 1' + 1'$.

Since 1990s, there has been a significant decline in the use of cytogenetic procedures for gene identification and location in wheat. The established cytogenetic knowledge and stocks developed since the 1940s, provided the framework for generating the current genetic reference maps used for more detailed molecular mapping aimed at gene cloning and isolation.

Interspecific Crosses and Gene Transfer

Common wheat can be crossed with all *Triticum* species and with many of its relatives in the Triticeae. The amount of chromosome pairing and fertility of such hybrids determines the methods used to attempt to introgress genetic material and useful agronomic traits from the related species to wheat. The most common and useful crosses for hexaploid wheat improvement have been those with close relatives such as tetraploid wheats and *Ae. squarrosa*, but there are some very successfully exploited introgressions from species of more distantly related genera such as *Thinopyrum*.

Once an accession with a trait of interest is identified in a related species, the first step is to produce a hybrid and to determine if such hybrids are fertile when self-pollinated or when backcrossed, particularly as female parents, with wheat. Bridging crosses and/or embryo rescue may be useful in achieving the fertility needed to undertake the transfer. Hybrids with at least some chromosome pairing are often sufficiently fertile to enable the transfer process through normal genetic recombination. Hybrids with little or no chromosome pairing sometimes form chromosomally doubled amphiploids, or partial amphiploids, through generation of restitution nuclei, or may undergo chromosome doubling in response to treatment with colchicine. Both backcrossing and amphiploids have been used to transfer genes from diploid wheat (via AAB, AABD or AAAABB bridging crosses) and *Ae. squarrosa* (via ABDD or AABBDD hybrids).

These transfers take advantage of normal homologous chromosome pairing.

Hybrids of amphiploids and partial amphiploids with wheat show normal chromosome pairing of the common wheat chromosomes with the additional "alien" chromosomes occurring as unpaired univalents. Backcrossing and selection for a trait or chromosome of interest results in recovery of single monosomic addition lines ($2n = 43$, $21''_{W} + 1'_{A}$). Such alien chromosomes have the ability to substitute for their wheat homeologs to produce 42 chromosome derivatives ($20''_{W} + 1'_{A}$) which approach normal wheat in vigor and fertility.

Progenies of monosomic addition lines, or preferably hybrids of alien substitution lines and wheat ($20'' + 1'_{W} + 1'_{A}$), can be used to select for translocation events that involve the alien chromosome and, most frequently, the unpaired wheat homeolog. Such translocations may occur spontaneously and often involve entire arm-centric fusions following misdivision, or may be induced by genetic procedures or by radiation with X-rays or fast neutrons. Through the use of further hybrids with some genotypes of *Ae. speltoides* or related species, deletion of chromosome 5B or mutants with disrupted control of strict bivalent pairing (*ph* mutants), homeologous chromosomes can be induced to pair and recombine with each other, including the homeologous alien chromosomes. Potential recombinants can be selected from progeny populations that appear to segregate in Mendelian ratios in contrast to the markedly reduced transmission rates of unpaired alien chromosomes. Candidate recombinants can be confirmed by meiotic chromosome pairing, C-band analyses, or by *in situ* hybridization using genomic DNA from the donor species as a dispersed probe. Obviously, small homeologous chromosome exchanges are most likely to be successfully exploited in agriculture because they should have minimal disruptive effects on inheritance and reduced likelihood of carrying undesirable genetic material. However, there are exceptions and the most widely exploited alien genetic transfer in wheat involves the replacement of the entire short arm of chromosome 1B with the short arm of 1R from cereal rye. The added rye segment carries genes for disease resistance and higher yield and better adaptation under certain conditions, but can have detrimental effects on bread-making quality.

This process of alien gene transfer, chromosome engineering, is not different in concept to that of genetic engineering where cloned genes at the DNA level are inserted into a chosen genotype. Transformation, however, is independent of sexual compatibility and can be carried out with genes isolated from another genotype of the recipient species or genes isolated from any source.

Wheat Genetics

Despite the known evolution of tetraploid and hexaploid wheat and the presence of common traits in these species and in the known ancestors and related species, not all traits in polyploid wheat are controlled by triplicated and duplicated genes. Some genes apparently have been mutated or lost entirely from the genome. The genes controlling some traits are clearly triplicated at corresponding or orthologous sites in each genome (for example, the *R* gene series in group 3 chromosomes controlling red kernel color) whereas other traits seem to be affected by single genes of major effect (e.g., the squarehead or nonspelt gene *Q* on chromosome 5A) or by multiple genes located on nonhomeologous chromosomes (e.g., the strong awn inhibitors on chromosomes 4A, 5A, and 6B). Triplicated traits such as red kernel color may be controlled by one, two, or three dominant genes depending upon the particular cultivar, or the kernel may be white. In contrast, the presence of ligules (compared with nonliguled variants) in common wheat is determined by genes in chromosomes 2B and 2D, whereas in tetraploid wheat, only the gene in 2B is present. Because the ancestral A genome species, *T. monococcum* and *T. urartu*, and all related diploid species are liguled, it seems the orthologous gene in chromosome 2A was lost (null allele) in polyploid wheat. Using this knowledge, alien chromosomes of homeologous group 2 can be selectively added to wheat using a liguleless wheat stock as the recurrent parent.

Despite the powerful techniques of genetic analysis that became available with aneuploidy, the genetic map of the large wheat genome continued to be sparsely populated. This was alleviated initially by the study of isozyme variation. More than 25 proteins, and often multiple forms of related enzymes, such as the esterases, were identified and characterized by electrophoresis. Many but not all allozymes were determined by orthologous gene sets. Individual electrophoretic bands were located to chromosomes and chromosome arms using nullisomic-tetrasomic and ditelocentric lines, and allelic variation at some loci enabled genetic mapping. However, allozyme analysis did not provide the high level of variation and number of loci that was being sought. Moreover, each protein had to be extracted, separated, and stained by individual techniques, and the overall process was expensive and tedious.

Opportunities for more detailed genetic analysis of wheat became available firstly with discovery and use of restriction enzymes and RFLP analysis, and later, with techniques for studying DNA polymorphism based on the polymerase chain reaction

(PCR) protocol. As with allozymes, electrophoretic bands were related to chromosome arms, but again the levels of allelic variation determined with RFLPs was relatively low in wheat compared with barley and maize. RFLPs were usually triplicated in orthologous sets. Despite the relatively low levels of polymorphism, many RFLPs were mapped and the information obtained contributed to a backbone of reference points on the wheat genetic map.

More recently, PCR-based microsatellite or simple sequence repeat (SSR) techniques provided an expanding number of chromosomally unique polymorphisms that can be readily mapped. Large "banks" of these have been developed for use by restricted "consortium" groups, or are available in the public domain. Microsatellites are the current tools of choice being applied to the rapidly expanding application of marker-assisted (marker-linked) selection in wheat improvement.

With increasingly detailed genetic maps, it became apparent that expressed genes are not evenly distributed throughout the large genome. Comparative physical and genetic maps showed a clear clustering of mapped genes to the terminal regions of chromosomes. For example, chromosome 1BS has a visible restriction about two-thirds of its length from the centromere. Most, if not all of the mapped genes in 1BS are located in the satellite demarcated by the restriction.

A Wheat Gene Catalog

Since 1968, wheat researchers have maintained a wheat gene catalog that ensures that genes are named in accordance with accepted rules. The catalog provides relevant information for each named gene, including attributes such as dominance, or origin if from an alien source, synonymous names, chromosome and arm locations, available genetic stocks in increasing order of complexity, and for genes determining morphological, quality, and disease traits, proximity to molecular markers. Catalog supplements are published annually and complete revisions occur at five-yearly intervals.

Genetics of Quality Traits in Wheat

Wheat is an important foodstuff for mankind because of its unique quality characteristics and the fact that large quantities of grain can be produced, harvested, stored, and transported in an efficient way. Its ability to produce a wide range of products is determined by the starch characteristics of the endosperm and the proteins that constitute $\sim$6–15% of the milled products. The main storage proteins, the glutenins and gliadins, determine dough strength, extensibility, and elasticity. The glutenin genes are classified as high-molecular-weight (HMW) glutenin genes located in the long arms of group 1 chromosomes and the low-molecular-weight (LMW) group located in the short arms. Up to five orthologous groups of gliadin genes occur in chromosomes of homeologous groups 1 and 6. Relative amounts of protein in wheat grain are largely environmentally influenced, but there are also genetic components for which group 5 chromosomes were particularly implicated.

Grain softness in common wheat, conferred by a dominant gene on chromosome 5DS, determines the milling characteristics and hence its suitability for the manufacture of specific products. Mutations in an orthologous series of waxy proteins (GBSS) in chromosome 4AL (translocated from 7BS), 7AS, or 7DS can, in various combinations, enhance the suitability of flour for noodle production.

The Genetics of Adaptation

Wheat cultivars used throughout the world were chosen pragmatically by farmers to suit the agronomic and climatic constraints of the environments in which they were grown. The genes that determine the growth and flowering characteristics include those responsible for response to vernalization, response to daylength, and earliness per se. In common wheat, there are up to five orthologous groups affecting vernalization response, one orthologous group (chromosome group 2) affecting daylength response and several diversely located genes for earliness per se. Nil or reduced vernalization response and reduced daylength response are conferred by dominant alleles.

Reduced plant height and increased straw strength were strongly selected by breeders in order to achieve higher yields through higher harvest index and reduced lodging. While the gibberellin-insensitive *Rht-B1b* and *Rht-D1b* alleles in chromosomes 4BS and 4DS were the choice of the Green Revolution, these alleles limit expression of coleoptile length, often resulting in low seedling emergence attributes for planting in dry environments. Consequently, attempts are being made to exploit alternative alleles at these loci, or various gibberellin-sensitive *Rht* genes in order to improve seedling vigor.

The Genetics of Stress Resistance

There are reports of genetic variation for tolerance to drought, freezing (leaf tissue), frost (spikes and flowers), heat, salt, certain herbicides, and to both mineral deficiencies and toxicities. In some instances,

major genes were documented, in others such as drought and heat tolerance, variability was largely quantitative.

Biotic stress resistances were found to have both qualitative and quantitative genetic bases. For diseases caused by highly specialized, pathogenically variable obligate pathogens such as the rusts, powdery mildew, and some smut pathogen species, as well as the Hessian fly pest, resistances were characterized in terms of several to many genes, each of large effect. For less specialized pathogens (and pests) such as those causing root rots and *Fusarium* head scab, individual gene effects were not so obvious, but there has been significant progress in genetic analysis using quantitative trait loci (QTL) mapping.

A significant recent development for the important leaf rust and stripe rust diseases has been increased emphasis on analyzing and exploiting durable adult plant resistances (APR). The genetics of durable APR have indicated oligogenetic additive combinations of genes, which individually confer relatively low levels of resistance. These findings offer the breeder the choice of selection for high levels of resistance in the disease nursery, predicting that agriculturally acceptable phenotypes will have gene combinations. To achieve this major genes should be avoided in crossing programs, or nullified in segregating populations by using appropriate virulent pathotypes for disease screening. Alternatively, specific molecular markers, if available, enable such genes to be combined in a planned way.

Concluding Remarks

The methods of genetic analysis of wheat have evolved since 1990s, from a strong effort on cytogenetics to an almost exclusive emphasis on molecular approaches. Cytogenetic stocks and knowledge enabled the construction of basic molecular framework maps to which the emerging molecular mapping data were referenced. With the rapidly increasing marker density of the genetic map, and current methods of discovering DNA polymorphisms, there is an expanding effort on gene characterization by heterologous homologies and gene isolation in wheat, as well as the increased application of marker technology and transformation in both wheat and durum improvement.

Wheat breeding is the exploitation and fixation of genetic variation by selection and evaluation for the benefit of mankind

Origin of Wheat

There are two known main species of wheat: common bread wheat (*Triticum aestivum* L.) and pasta or durum wheat (*Triticum turgidum* L. subsp. *turgidum* conv. *durum*). These occur as natural interspecific hybrids.

The wheat progenitors (e.g., *Triticum monococcum*, *Aegilops speltoides*, and *Aegilops tauschii*) are diploid grasses, having seven pairs of chromosomes ($2n = 14$). The natural chromosome complement or genome of each grass is unique, which supplies the grass its species attributes.

Through many natural hybridization events, possibly over thousands of years in the West Asian region, a range of natural polyploids developed. The best known of these are durum wheat and common bread wheat.

Durum wheat is a tetraploid ($4n = 28$). It was derived from the natural hybridization of two diploid grasses, *Triticum monococcum* (A genome) and *Aegilops speltoides* (B genome), giving it a genomic constitution of AABB.

Common bread wheat is a hexaploid ($6n = 42$), a result of a natural hybridization event between *Triticum dicoccoides* (AABB) and *Triticum tauschii* (DD). Bread wheat has a genomic constitution of AABBDD.

While durum and bread wheats are tetraploids and hexaploids, respectively, at mitosis and meiosis they both behave as diploids, forming 14 and 21 pairs of chromosomes, respectively. This is because wheat has a gene that confers pairing of the chromosomes at these times in a homologous fashion, rather than across the genomes. The recognition of a naturally occurring line deficient in the pairing homologous gene allows wheat to pair across the genomes at both meiosis and mitosis. This means that genetic recombination can occur across the genomes, rather than between chromosomes within a genome. This ability to have wheat pair either within or across its genomes facilitates the movement of genes between wheat and its near and distant relatives, making wheat relatives a very valuable source of genetic variation for pest and disease resistance, grain quality, etc.

The Earliest Plant Breeders

The earliest wheat breeders were undoubtedly man's forebears, the hunter-gatherers. Most primitive wheats contain a gene for brittle rachis, where the main branch of the flower fragments at each spikelet when mature. Harvesting would entail having to pick up each spikelet from the ground. A naturally occurring variant keeps the head intact. The ease with which this type could be harvested would have resulted in its quick selection as the preferred type by early hunter–gatherers.

Working at the Phenotype Level

Just like the hunter-gatherer, today's wheat breeder has to work with the phenotype, or what we see when we look at the plant. The phenotype is influenced by both the genetic constitution of the plant, as well as the environment in which it is grown, plus the manifestation of the interaction between the genotype and its environment, or the genotype–environment (G–E) interaction. This can be expressed as follows:

$$\text{phenotype} = \text{genotype} + \text{environment} + \text{G–E interaction}$$

As long as the breeder has to work with the phenotype, the design and implementation of all plant breeding is based around this simple but fundamental equation.

It is clear from this statement that all three factors can influence the phenotype. Critically, for breeding to be effective, an understanding of how all components interact on the phenotype is fundamental to success for any target region.

Phenotypes in which the environmental and G–E components prevail will, by definition, alter in their expression when the environment changes. This will result in differing performance of a genotype from location to location and from year to year, resulting in the absence of genetic progress.

On the other hand, phenotypes where the genotype component prevails and where the influence of the environment and G–E components are minimized will result in a consistent performance across locations and years. Under this scenario, genetic advance is made, resulting in the identification of the genetically superior wheats that get released as new varieties.

Understanding the Environment and the Setting of Breeding Objectives

A thorough knowledge of the environment is fundamental, as it is the environment that determines breeding objectives. In its entirety, the environment consists of the soils, climate, and the biological environment in which the plant has to live. The breeder also has other environmental dimensions to consider such as the financial and physical resources available to the breeding program, access to support scientific disciplines and enabling technologies as well as the grain quality demanded by the major markets to which grain may be sold.

The Environment

Soils

The soil provides the plant with its base for growing, as well as its water and nutrients. Soil structure impacts on water penetration and holding ability. High-clay-content soils generally have superior water-holding capacity compared with sandy-clay loams or deep sands. Factors such as pH, with its effect on plant growth, nutrient availability, and effect on factors toxic to plant growth such as free aluminum at low pH, high levels of available boron in ex-marine soils, unavailability of essential nutrients such as zinc at high pH, unavailability of minor nutrients such as copper under waterlogging conditions, etc., all can have dramatic impacts on plant growth and, if not understood, can reduce genetic gain by appearing to be uncontrollable G–E interactions. However, when properly understood, the production environment can be managed using agronomic approaches. In combination with genetic variability that exists for most of the above aspects, these factors can be ameliorated.

Climate

The amount of rainfall the wheat crop receives and the timing of the rainfall events over the growing season impact on plant growth via the obvious extremes of waterlogging or drought. Rainfall and soil fertility are two of the major factors determining grain yield and quality. Even transient periods of both events can have dramatic impacts on plant growth and thus on grain yield and quality.

Temperature has a regulating influence on plant growth. Extremes such as high temperatures cause heat stress and drought, with downsides on yield and quality. Cold temperatures during winter slowdown growth, or lead to soil freezing, and the need for breeders to incorporate winter hardiness in most of the major winter wheat-growing areas of the world.

Transient periods of low temperature to below 0°C at critical stages of plant growth, such as from terminal spikelet formation through to flowering, can cause severe yield losses as a result of frost damage. In most areas of the world, the practice is to breed for frost avoidance, by delaying flowering to a time of more acceptable frost risk. This commonly means that flowering is delayed, so that grain filling has to take place under conditions of increasing temperature and decreasing availability of water.

Wind increases transpiration from plants, so in dry areas this places crops under risk of increased moisture stress (drought at its severest). In combination with high temperatures during and after flowering, the grain-fill period experiences transient periods of moisture stresses. Breeders need to select and evaluate their materials under similar conditions to which they will be grown in order to produce varieties that can tolerate such conditions. Wind also demands that ripe crops can stand and ripen without lodging and or shedding their grain prior to harvest.

Biological Component

The interaction between soils and climate provides the conditions for organisms, both favorable and destructive to plant growth, to prosper.

Favorable soil conditions like vesicular arbuscular mycorrhizae (VAM) are important for healthy plant growth. The availability of moisture and nutrients is affected by what happens in the rhizosphere. This can also result in conditions where fungi, bacteria, viruses, and nematodes pathogenic to wheat plants can prosper.

A wide range of fungi can infect wheat roots and their crowns, causing major yield losses. These include a range of Fusarium species, common root rot, Rhizoctonia root rot, a number of viruses, and plant nematodes. It is the environmental conditions in conjunction with a susceptible host plant that predisposes the plant to attack. An example is snow mold, where it is the amount and period of snow cover that determines the extent and severity of disease development.

Above the ground, it is again the interaction of all the climatic components, in conjunction with susceptible host plants, that determines which plant diseases and pests will prosper, and the range is vast.

The major foliar fungal pathogens are the rusts (stem, leaf, and stripe), the septorias (tritici and nodorum blotch), powdery mildew, and yellow (tan) spot. Each of these has unique sets of environmental conditions for development, mostly governed by the length of the dew period on the leaves for spores to germinate, and then in the cases of the

septorias and yellow spot rain drops for splash dispersal of spore to adjacent plants and new leaves of existing plants.

A range of viruses can also cause yield loss. Some require vectors for transfer between plants, such as barley yellow dwarf virus that is dispersed by aphids and wheat streak mosaic virus that is spread by the wheat curl mite.

A variety of insect pests attack wheat plants causing yield and quality losses. Examples are: wheat stem saw fly, which lays its larvae into wheat stems and the metamorphosis of the larvae weakens the stem, leading to straw breakage and lodging; cereal leaf beetle, which eats the epidermal tissues from leaves, thereby reducing photosynthetic area and causing yield loss; the cinch bug and some aphids, which feed on developing grains, releasing proteolytic enzymes into the grain and causing deterioration of the gluten proteins responsible for dough quality.

This brief overview of the major pests and diseases of wheat is intended to highlight that they are many and varied, and they cause major losses in both yield and quality. As a result, most wheat breeding programs direct the major share of their resources to breeding for resistance. In order to effectively prioritize which resistances should be addressed by a breeding solution, breeders must have a comprehensive understanding of the environment of their target breeding area.

For the full range of pests and diseases of wheat, biological variability exists. For the breeder, this means that one source of germplasm rarely is effective against all races, strains, or pathotypes of the pest or disease. Thus, effective breeding requires ongoing access to resistant germplasm and reliable screening tests.

Grain Quality

Major areas of world wheat production are often located at considerable distances from where the grain will be consumed, resulting in the sophisticated grain handling and transport systems as part of grain trading. Increasingly, grain is traded on the basis of rigid quality specifications of dryness, cleanliness, and protein content. More discriminating markets have even tighter specifications relating to dough properties and end-product quality. It is this diversity of requirements that breeders must satisfy when setting quality objectives for their breeding programs.

The environment of the target breeding and production region influences the quality of wheat that can be grown in any area. The production environment has a major impact on grain protein content, one of the major specifications upon which grain is traded internationally. For example, dryer regions tend to be lower yielding and favor the production of higher-protein, better-quality wheat.

To set effective market-based quality objectives the breeder needs a reliable supply of market intelligence that has been interpreted into what is achievable by breeding. In most of the large wheat producing and exporting countries, breeding programs obtain this information from grain traders, processors such as millers and bakers, and/or grower-supported marketing and research agencies.

Assembling and Creating Genetic Variability

Genetic variability is the cornerstone of wheat breeding. Variability can be sourced from bread wheat or its near and distant relatives. Traits can be introgressed into bread wheat from these sources by using conventional hybridization techniques. In interspecific or intergeneric hybridizations the use of chromosome doubling may be required to get a balanced chromosome complement for successful cell division of the embryo and the resultant plant.

With the advent of molecular biology, traditional interspecific, intergeneric, and plant type barriers to gene transfer have been removed. By isolating the gene for a particular trait and inserting it into a new host by a range of techniques (e.g., biolistic bombardment or Agrobacterium transfer), the gene becomes part of the host DNA, replicating itself at cell division and expressing itself in plant development. The development of such genetic engineering techniques considerably enhances the range of genes available to the modern plant breeder.

Traditionally, breeders have gone to other breeding programs or to major germplasm collections to source their genetic variability. Utilizing genetic variability is always done in a targeted manner, with the breeder seeking new genes for an agronomic, disease resistance, quality- or yield-related trait. Transfer of the new gene is usually by conventional hybridization, followed by cycles of selection until the new gene is fixed in its new background. To facilitate transfer of new genes, some knowledge of the inheritance of the trait and the ability to select for it in its new background are essential.

Role of Germplasm Collections for New Trait Discovery

Large collections of wheat are kept in international collections (link to USDA Beltsville, Australian Winter Cereals Collection, Vavilov Collection, CIMMYT,

etc.) and are major sources of variability utilized by breeders. In some instances passbook data is held on entries in these collections. However, often when a new disease or pest problem arises, the breeder has to systematically screen the collection for sources of resistance. As this is done, data are fed back to the collections, thereby creating some passbook data for future use. However, in the case of a new disease or change in an existing disease, the breeder usually has to go back to the collection and commence the screening process all over again, as it is only with virulence in a pathogen that new resistance in a host plant can be identified. Until we understand the genetic basis of what actually confers resistance at the DNA level, this cyclic process of screening germplasm collections will continue as new problems emerge.

Hybridization Systems

Wheat is a self-pollinating crop and so lends itself to hybridization by a range of methods. Breeders design their crossing programs so that the resulting populations produced will segregate for all the traits desired in the new varieties. Breeders choose one of the parents to become the female of the cross, and affect this by removing the anthers from all florets of the ear. Hybridization is completed a few hours to a few days later by transferring pollen from the plant designated as the male. This is done using a range of methods, with the transfer being completed using tweezers to shake the pollen from individual anthers onto the receptive stigma, or by cutting back florets of the designated male plant so that anthers are exposed. The dry air causes them to dehisce, and the male plant is then shaken or twirled over the stigma, thereby effecting pollination.

Other means for hybridizing wheat include the use of cytoplasmic male sterility–nuclear fertility restoration mechanisms or the use of chemical hybridization agents. Both of these systems still rely on making one of the parents the nominal female, while pollen is transferred from another parent chosen as the male of the cross. Both of these mechanisms, while useful for crossing, are better deployed for making hybrid wheat where the advantages of heterosis (hybrid vigor) can be captured.

Crossing Strategies

Choice of crossing strategy depends on the range of traits available in the parents and those desired in the progeny of a cross. If all the desired attributes can be obtained from just using two parents, A and B, then the straight cross A/B strategy can be deployed. If one of the parents (A) has more desirable traits than the other, then to increase the frequency of the desired genes from A a further cross to that parent can be made, making for an A/B//A crossing strategy.

When all the desired traits cannot be assembled from a straight crossing strategy and three parents are needed (A, B, and C) to get all of them in the progeny then a three-way crossing system can be used, such as A/B//C.

When a variety has most of the traits desired, but has had a resistance breakdown or can be enhanced by the addition of a new resistance or trait, then the new gene(s) can be rapidly introgressed using the backcross crossing strategy. If the new resistance gene is dominantly inherited then all that is wanted from this donor parent is that gene, so the original variety becomes the recurrent parent and repeated cycles of crossing between the recurrent parent and the F1 generation can be made until the desired percent of the recurrent parent is recovered. The straight cross F1 contains 50% of genes from each parent. The first backcross to the recurrent parent increases the frequency of recurrent parent genes to 75%. Subsequent backcrosses increase the gene frequency to 87%, 93%, 96%, 98% for the second to fifth backcrosses, respectively, and so on.

When deploying the backcross breeding strategy to recessively inherited genes, it is necessary to allow the first cross to go to the F2 generation and then screen for the presence of the new gene or trait, prior to making the next backcross. At each backcross cycle it is necessary to go to the F2 and conduct screening for the new trait prior to crossing to the recurrent parent.

Selection and Evaluation Systems and Breeding Methods

Factors Influencing the Sequence of Trait Selection and Choice of Breeding Method

Many factors influence the sequence in which traits are selected in a breeding program. These include the economic importance of the trait, its heritability, the availability of simple and effective selection methods, cost of the selection process and the extent of resources available to the breeding program. As a result, traits with high heritability and essential components of any new variety, such as most agronomic attributes such as flowering time, straw strength, and lodging resistance and many disease resistances are selected on a single plant level commencing in the F2 generation and usually fixed early in the breeding cycle (by F3 or F4 generation). More difficult to select traits like grain yield and quality are selected later in the breeding cycle (F4 onwards)

and this is done on a progeny basis in plots rather than a single plant basis.

There are many different ways in which breeders can manage material flow in breeding programs. Choice of method depends on many factors, including cost of variety development, which makes the shortening of the breeding cycle a high priority, resources available to the breeding program and the availability of effective selection methodologies for the target traits.

Pedigree method This is the method of choice where disease resistances are the priority traits that must be incorporated into new varieties. The pedigree method allows for simply inherited, often single-gene traits to be selected and fixed through repeated cycles (2–4) of selection until homozygosity is achieved. To shorten varietal development, this method is often combined with the use of two or more field-grown generations per year (Figure 1).

Modified pedigree In this process the basic pedigree cycle is followed, but with the addition of a round of yield evaluation and or quality testing as early as possible, F3 or F4, in order to remove low-yielding and poor-quality families from the breeding program.

Single-seed descent This rapid method allows for up to four generations per year using growth chambers and glasshouse conditions (Figure 1). A population of 200 or more seeds is planted and only single tiller plants produced by manipulating the watering and nutrition regime to speed up the growth of plants. At harvest, one seed from each plant is taken and planted again for the next generation. This process is repeated until plants are advanced to between the F4 and F6 generations. Seed is then increased and planted in the field in observation rows or yield plots. The advantages of single-seed descent (SSD) are speed combined with cycles of recombination, giving the possibility of desirable recombinants being produced.

Doubled haploid or dihaploid development In this method, F1 seeds are produced by conventional crossing techniques using the two parents that between them have all the traits desired in the new variety (Figure 1). Doubled haploids can be produced from microspore culture, but the wheat–maize method is the most widely used system. In the wheat–maize system, F1 seed is made by hybridization, the seeds planted and their flowers emasculated and pollinated with maize pollen. A haploid (a plant with single chromosome of each of the 21 bread wheat pairs) starts to develop. This is saved using an embryo rescue technique and allowed to grow into a haploid plantlet, which is then treated with a chromosome-doubling agent such as colchicine, nitrous oxide, or caffeine to produce a diploid plant. Seeds from these plants are instantly homozygous for all genes, thus imparting the major advantage of this breeding system, namely, that it takes material to true breeding status in less than one year, thus considerably shortening the breeding cycle.

Early, Mid-, and Late Generation Selection

In the early generations, the focus is on selection of traits of highest heritability. These are usually agronomic attributes and disease resistances. In the mid- and later generations, irrespective of what breeding method a breeder chooses to use, selection is about validating performance of breeding lines, demonstrating their merit for potential release as new varieties. This usually involves the use of replicated, multi-site, multi-year yield and quality evaluations to gather the data needed to support the decision to bulk up seed for release. Most breeding programs consider that three years of such evaluations are needed to demonstrate the reliability of any potential variety.

Emerging and Enabling Technologies

One of the most exciting emerging technologies is the use of marker-assisted selection (MAS). The value of MAS is that it shifts the basis of selection from the phenotype level to the gene level. The requirement for it to work effectively is that the markers are either closely linked to, or reside within the gene to be selected.

MAS provides a more accurate and reliable method of selection as it is not influenced by the effect of the environment. Hence, it is extremely attractive to breeders for traits that are difficult and time consuming to screen for, and are highly modulated in their expression by the environment.

However, one of the major limitations to the deployment of MAS in bread wheat has been a lack of polymorphism that has often expressed itself by a lack of robustness of a marker across a range of breeding populations. MAS is being deployed widely and successfully in a range of other broad acre crops, so while the benefits to wheat breeding are recognized, the major benefits are yet to be realized.

Use of the genetically modified organism approach is in its infancy in wheat breeding. These technologies remove species and genus barriers to gene transfer, so they considerably expand the range of genes available

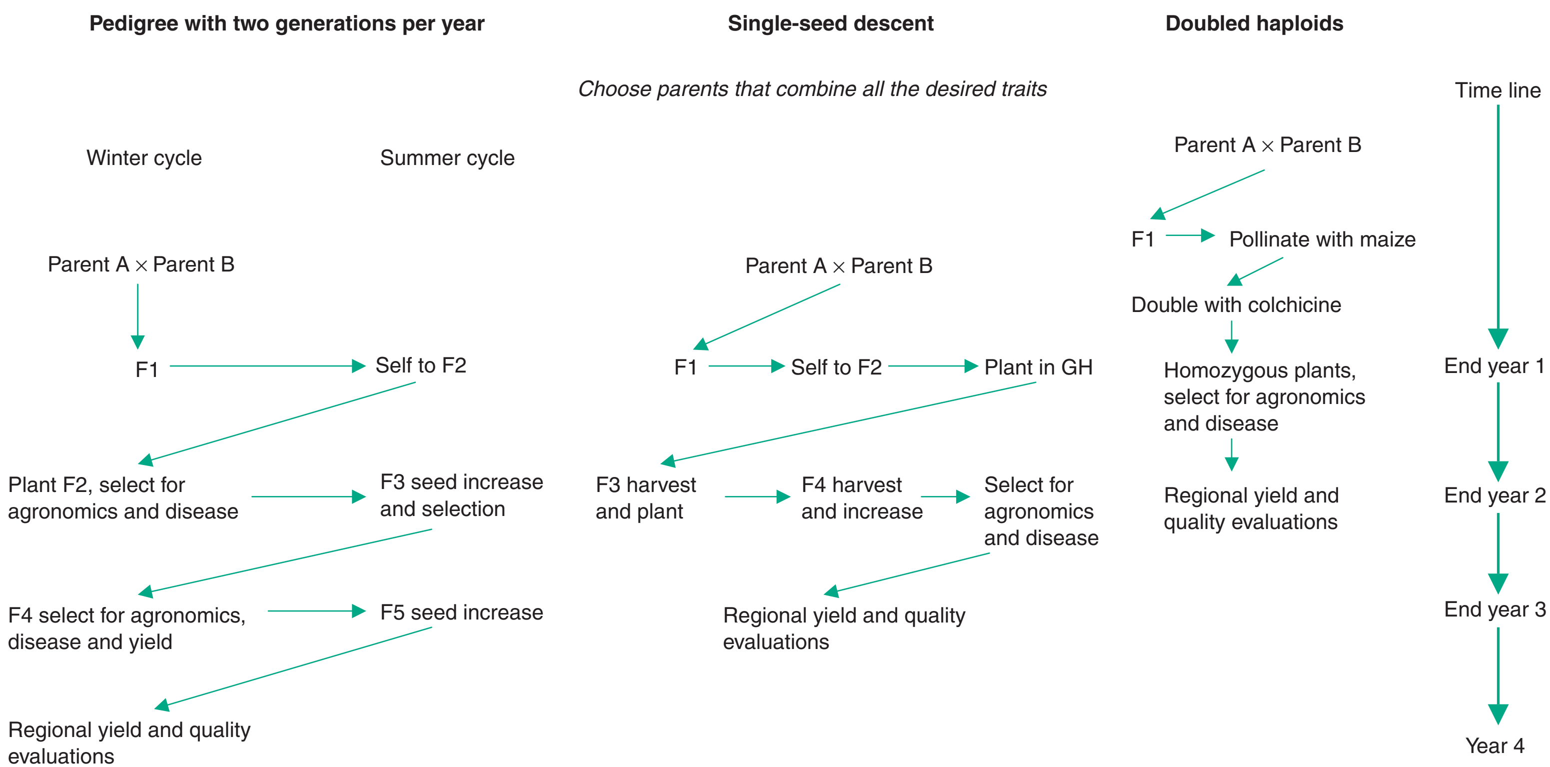

Figure 1 Schematic of three breeding methods.

to the wheat breeder. Currently the processes of inserting the genes into wheat breeding material means that the position the gene inserts itself into the host DNA is random, so success rate of gene expression is low.

As gene-splicing techniques improve, the success rate can be expected to improve. While the success rate of current methods remains low, GMO's offer breeders new genes, but these will need to be transferred into adapted backgrounds for release as new varieties using conventional breeding methods such as hybridization and selection. Backcrossing is the preferred method for rapidly transferring GMO traits into adapted wheat backgrounds.

Varietal fingerprinting is another useful breeding aid where both the DNA complement of a recurrent parent and a DNA-based marker for the gene to be introgressed in a backcross breeding program can be tracked at the DNA level. The use of these combined strategies will shorten the breeding cycle by earlier recovery of sufficient contribution of the recurrent parent DNA at an earlier stage in the backcross process. This technology will also be increasingly used to identify breeding programs for varietal identification at the point of sale for integrity of marketing and trading grain and for intellectual property issues associated with the protection of plant breeders' rights.

Wheat Breeding as Part of Supply Chain Management

Modern wheat breeding is just one part of a sophisticated supply chain, whereby all parts of the chain are important in adding value to a major food source. All members in the supply chain can have a major impact on the overall product as it moves through the chain, so the more these components can be integrated the more efficient the process, and the less downside on the quality of the end product. This demands a good information flow up and down the supply chain. With the wheat breeder sitting at the end of the supply chain most distant from the consumer, the effectiveness of information flow and the quality of that information are critical for effective wheat breeding.

Introduction

Wheat is the world's most popular crop. It is grown over a large area and under a wide range of conditions and provides more nutrition to humans than any other species. Over 580 million tons (Mt) is produced annually on 220 million hectares (Mha), an average of 2.66 t ha^{-1} (Table 1). Ripe grain is harvested and a new crop is planted somewhere in the world during every month of the year. Wheat is also the oldest of crops, one that is grown in over 120 countries with many different technologies and traditions.

Production of wheat has increased ~100% during recent decades, the maximum increase seen in any food crop. Improved agronomic practices and new varieties account equally for over 80% of the gain and increased area for less than 20%. The extreme conditions for growing wheat, the many classes that are produced, and the numerous cultural traditions create highly diverse agronomic practices. This article describes wheat in relation to its agronomy, major factors that affect its productivity, and the different agronomic practices for its production.

Wheat in Relation to Its Agronomy

The Wheat Plant

Wheat is a member of the grass family (Gramineae) that produces an edible one-seeded caryopsis called a berry, grain, or kernel. The seed normally germinates within 1 week after planting and the first true leaf, the coleoptile, emerges from the soil. Each plant produces five to seven leaves from a growing point, or apical meristem, which then differentiates from a vegetative to a reproductive structure to form a spike that bears the grain. Tillers develop in the axils of leaves, giving each plant three to a dozen or more spikes depending on conditions, a trait that makes wheat highly adaptable to different environments.

Table 1 Area, production, and yield of wheat by major exporters, major importers, and other countries during 2000–01[a]

	Countries			
	Major exporters	*Major importers*	*Other*	*World*
Area (Mha)	69.69	91.08	58.78	219.55
Production (Mt)	232.34	209.90	141.57	583.82
Yield (t ha^{-1})	3.33	2.30	2.41	2.66

[a] Data from Production Estimates and Crop Assessment Division, Foreign Agricultural Service, US Department of Agriculture.

Two root systems form on wheat: seminal roots from the embryo of the seed and adventitious roots from the coleoptile and tillers. The adventitious system is usually more extensive and may spread to several meters below the plant to absorb moisture and nutrients from the soil.

Grain growth begins with anthesis or flowering, when pollen is released from the three stamens in each floret and deposited on the stigma of the ovary. Wheat is 95–98% self-pollinated and little exchange of pollen with other plants, or out-crossing, occurs. Growth of the grain (maturation) proceeds in a sigmoid fashion, with a lag period for an increase in cell number, a linear period for an increase in cell mass, and a plateau as the grain approaches maximum weight (physiological maturity). The grain then ripens as the moisture content decreases from 35% to 40% down to 14%. Most varieties also have an after-ripening period of 1–4 weeks, during which the grain loses dormancy and becomes capable of germinating.

Yield components of wheat – the constituents that determine the harvest – include the plant density (number per area), tillers per plant, spikelets per spike, kernels per spikelet, and the mass per kernel. Agronomic practices strive to optimize, not maximize, each component because of the compensation among them. For instance, high plant density reduces tillering, and excessive tillers may decrease the number of kernels in each spike.

Classes of Wheat

Two of the many types of wheat that are grown throughout the world, common wheat and durum, are most prominent. Common wheat (*Triticum aestivum* L.) is hexaploid ($6N = 42$) and occupies ~90% of the world wheat cultivation area. It includes classes with spring and winter growth habit, hard and soft endosperm, and red and white pericarp (seedcoat).

Spring and winter growth habit do not denote the season that the crop is grown but instead indicate whether the plant requires cold to change from vegetative to reproductive growth, a process called vernalization. Spring wheat has no vernalization requirement, whereas winter wheat needs 1–6 weeks of ~5°C to induce reproductive growth. Wheat also

requires long or lengthening days of ~14 h to initiate flowering, except for varieties that are bred to eliminate daylength sensitivity and are said to be day-neutral. Varieties with a third growth habit, known as facultative wheat, do not require vernalization but have strong daylength sensitivity.

Hard wheat is used primarily for raised bread and buns, but is also satisfactory for steamed bread; flatbreads such as "chapatis," "tortillas," and "pieta;" and for Asian noodles. Soft wheat is used for cakes, pastries, flat breads, and crackers. White wheat is preferred by many consumers, particularly for cereals and whole-wheat products.

Durum (*T. turgidum* L. var. *durum*) is a tetraploid ($4N = 28$) and accounts for ~8% of world wheat production. It is more resistant to drought and heat than common wheat and is mostly grown in regions with considerable environmental stress. Nearly all commercial varieties have a spring growth habit. The grain of durum is extremely hard and is used mostly for pasta (macaroni and spaghetti), "couscous," and "burghul" but is also used for bread in some localities.

Club wheat (*T. aestivum* L. var. *compactum*) is a hexaploid that has spring or winter growth habit and red or white grain and is used for the same products as common wheat. Other specialty wheats include einkorn (*T. monococcum* L.), a diploid ($2N = 14$) and an ancient crop that is mostly grown in harsh environments in several European countries; emmer (*T. turgidum* L. var. *dicoccum*), a tetraploid used for bread and porridge; and spelt (*T. aestivum* L. var. *spelt*), an ancient hexaploid that is used for bread, "pilaf," and hot cereals. (*See* **Cereals**: Evolution of Species and **Wheat**: Genetics for the relationships among species of wheat and **Triticale** for a description of this durum × rye hybrid.)

Wheat has numerous uses other than as food. Considerable winter wheat is grazed for forage by livestock, and the straw left after harvest is used for bedding and feeding livestock, composting mushrooms, and making bricks and particle board. Much of the grain is fed to livestock in some countries, as are damaged or surplus grain and by-products from milling in other countries. Starch from grain has many industrial applications, including paper, adhesives, plastics, and replacement for milk and egg white in foods.

Wheat in Relation to Its Environment

Wheat is a cool-season species that does best in temperate regions with ample sunshine and moderate moisture. Few of the major production areas – the maritime region of Western Europe and high elevations in several parts of the world being exceptions – are highly favorable for wheat. Other crops that are more productive or more valuable are usually grown in amenable regions and wheat, being well adapted to stress conditions, is often the crop of choice in marginal areas.

Soil Factors

Poor soil conditions – low fertility, salinity, toxicities, waterlogging, and erosion – are major factors in the unfavorable environment for wheat. Nitrogen is the critical component of the protein that determines the food quality of wheat and is often the limiting soil nutrient for yield. Phosphorus is usually limiting after nitrogen and is particularly essential for grain growth. Potassium is especially needed for vegetative growth. Sulfur may be deficient in soils that are coarse and low in organic matter. Magnesium is not deficient for production of wheat in most areas, but marginal levels in plants may cause grass tetany in pasturing livestock. Iron may be deficient when the soil pH or manganese content is high. Copper deficiency occurs on soils that have high organic matter content, and zinc may be inadequate in soils that are eroded or low in organic matter. Responses to chlorine fertilizers have been reported in some regions, but the effect is from amelioration of foliar diseases and not a plant deficiency of the nutrient.

Salinity from accumulation of various salts in the soil has rendered parts of Asia, Australia, and elsewhere unsuitable for crops. The problem is most severe where irrigation water is high in salts or the water table is near the soil surface. Direct toxicity to wheat occurs when certain elements are highly available in the soil. Aluminum and sometimes manganese become toxic as a result of low soil pH, often from long-time application of nitrogen fertilizers. Other toxicities have been reported from excessive chlorine, boron, arsenic, molybdenum, and nickel. Hypoxia, or inadequate oxygen for plant growth, occurs where soil is waterlogged because of poor drainage, a high water table, or a shallow hard pan.

Drought is a perennial problem in many regions and an episodic problem in most other regions for wheat. Inadequate water is the major limiting factor for wheat worldwide, affecting production on an estimated 70% of the area in developing countries and at least as much in developed countries. Wheat has higher water use efficiency than most crops but still requires 1 mm per 10–20 kg grain ha^{-1} or 1–3 mm day^{-1} during early stages and 7–8 mm day^{-1} at anthesis.

Cold Temperatures

Cold injures plants directly or by causing them to heave from the soil, smother under ice, or desiccate, processes known collectively as winterkilling. Winter wheat hardens to cold during autumn, and the hardiest varieties can tolerate direct exposure down to $-18°C$. However, farmers may not plant the hardiest varieties because they often have lower yields than less hardy varieties; they may plant the crop too late for it to harden, or a snow cover may be missing to insulate the plants.

Winter wheat and spring wheat are often subject to late spring freeze injury. The plants lose tolerance to freezing as they develop and are easily injured by cold fronts or radiation freezing. Late spring freeze injury is particularly damaging during anthesis, when anthers may be destroyed by only $-1°C$ and the plants, being mostly self-pollinated, are sterilized. In far northern areas, late summer or early autumn freezes before wheat matures diminish the yield and quality of the grain.

High Temperature

High temperature during maturation affects wheat in many regions. The optimum temperature for grain growth is 15°C; higher temperatures accelerate maturation, reduce the yield, and alter the gliadin proteins that determine grain quality. High temperature is frequently accompanied by dry winds known as "Gan Zhe Feng" in China, "Sukhovei" in Russia, "Siroccu" in North Africa, and "Khamsin" in the Middle East.

Wind and Lodging

Wind causes soil to blow, particularly during spring when the soil surface is dry and the vegetative cover is sparse. Blowing erodes the soil and abrades the plants, causing them to desiccate. Wind also removes soil from around the roots of plants or deposits soil on top of them. Later in the season, wind causes grain-laden plants to lodge or fall over, especially when the stand is dense or growth has been stimulated by nitrogen fertilizer. Lodging reduces yield and complicates harvest.

Hail

Hail is a frequent hazard to wheat. Damage depends greatly on the plant developmental stage. Leaves are most labile at early stages, floral structures are susceptible before anthesis, and the grain shatters or dislodges from the spike at late stages.

Preharvest Sprouting

Preharvest sprouting of the grain occurs when persistently wet, humid conditions coincide with ripening. Varieties differ somewhat, but most white-grained wheats are much more susceptible than red wheats. Sprouting is most damaging to the quality of wheat for bread because of the high α-amylase enzyme activity that occurs; it is less detrimental to cakes and other products.

Biotic Factors

Weeds are common problems, often seriously reducing the yield and sometimes the quality of the grain. Most species compete with wheat for light, moisture, nutrients, and space. Others are allelopathic, producing chemicals that inhibit growth of the wheat plant. They also interfere with harvest and increase the moisture content of the grain, causing heating and molds. Some weed species cause off-tastes in the grain, which lower its value. Winter annual weeds, which germinate during autumn and complete their growth cycle the following year, are most detrimental to winter wheat and spring wheat planted during autumn. Summer annual weeds that germinate during spring and mature in summer mostly affect spring-seeded wheat but can also occur in sparse stands of winter wheat. Perennial weeds, which live indefinitely, are problems in both winter and spring wheat. (*See* **Plants**: Diseases and Pests and **Cereals**: Grain Diseases for other important biotic factors in wheat agronomy.)

Agronomic Practices for Wheat

Varieties and Seeds

More than 80% of the wheat area in developing countries and ~100% in developed countries is planted to modern varieties. Few true hybrids are grown because the seed is costly and the yield advantage is often small.

Varieties must be adapted to the local environment, resist indigenous biotic and abiotic stresses, and produce quality grain, in addition to yielding well. Most varieties are semidwarf, 60–80 cm tall, in contrast to traditional varieties that grow up to 120 cm in height. Semidwarf varieties do not produce more biomass, but they allocate more of it to the grain. They also respond to high plant density and high levels of nitrogen fertilizer by producing more grain instead of lodging.

Improved varieties are developed primarily by public agencies, such as government ministries and universities, in most countries except in western Europe and South Africa, where they are mostly supplied by private companies (*see* **Wheat**: Breeding). Once farmers receive a new variety, they usually save grain from each harvest for seed to plant the

next crop and only purchase commercial seed when a new, superior variety becomes available. Whatever the source, wheat seed should have a minimum germination of 85–90%, a minimum volume weight of 72 kg hl^{-1}, and be free of weed seeds and diseases.

Rotations and Tillage

Numerous rotations are used for wheat. Fallow, or leaving the land unplanted during alternate seasons, is common where annual precipitation is less than 400 mm. Some rotations include fallow with 2 years of wheat or wheat followed by another crop for two harvests every 3 years. Fallow benefits yield of the succeeding crop by increasing soil moisture and nitrogen and, in some cases, reducing pests.

Continuous wheat, i.e., growing wheat every year, is favored in some areas by the climate, tradition, or government programs. However, the practice often promotes buildup of diseases and weeds that eventually reduces wheat yields. Mixed farming systems that alternate wheat with other crops such as soybean, maize, cotton, and rapeseed alleviate these problems.

Double cropping, or growing two crops during the year, is practiced where precipitation and the growing season are amenable. Wheat is always the winter crop and rice, soybean, vegetables, or other species are the summer crop. Double cropping gives two crops every year, but yields are sometimes hurt when one crop creates unfavorable conditions for the other or late harvest of one delays planting of the other crop.

Tillage practices for wheat range from systems of no tillage to "the more you till the more you reap." An ideal medium for wheat varies among regions but always includes a firm, moist seedbed with a loose, cloddy surface. Surface residue from the previous crop is desirable for winter wheat in arid and temperate areas to hold moisture, prevent erosion, and trap snow. It is also usually desirable for spring wheat, but in some areas it may be buried by plowing in autumn to hasten drying of the soil for planting the following spring.

Conventional tillage for wheat in regions where soil moisture is adequate generally consists of plowing to a depth of 10–20 cm, disking, and harrowing. However, plowing is increasingly being eliminated, and only disking and harrowing are done. Where moisture is limiting, a chisel or sweep cultivator is often used to leave a "stubble mulch" to retain moisture and prevent erosion and is followed by disking or harrowing immediately before planting.

Zero or conservation tillage, a practice that is growing in some regions, involves planting wheat with no prior tillage of the soil. It generally provides an excellent seedbed for rapid germination and reduces costs and soil compaction. However, expenses for chemicals to control weeds and infestation of diseases and insects from residue of the previous crop are increased. Another form of direct seeding is practiced with the rice–wheat rotation in Southeast Asia, where wheat is sown on the soil surface after the rice is harvested. The system requires close control of soil water but gives a rapid stand of wheat without the cost and time of preparing the soil.

Farmers in some areas still till the soil intensively for wheat. In parts of South Asia, for instance, the soil is plowed 6–8 times with a tine-cultivator or disk harrow and then leveled with a wooden plank.

Planting

Timely planting is critical for productivity of wheat. Winter wheat should be planted early enough in autumn to allow two to three leaves to develop before winter. Early planting is often practiced when the wheat is to be grazed by livestock, but it may promote loss of soil moisture, diseases, and insects such as Hessian fly. Delaying planting, on the other hand, gives plants little time to develop the root and shoot systems and to cold-harden, reduces accumulation of snow, and may promote erosion.

Spring wheat is sown as soon as soil conditions permit in temperate areas to encourage early plant development; avoid the hot, dry periods of summer; and in far northern areas, enable maturation before frosts occur. In milder regions, where spring wheat is planted during autumn, timely planting is also important for avoiding unfavorable summer conditions but is sometimes difficult when summer crops are harvested late.

Seeding rates for wheat range greatly from 25 kg ha^{-1} under arid conditions to 200 kg ha^{-1} for intensive management under ample soil moisture. Lower rates are sometimes used for increasing seed supplies of new varieties and higher rates for wheat that is planted late or used for grazing. The goal of varying the seeding rate is to achieve a spike density that is optimum for the moisture supply. This ranges from $\sim$200 spikes m^{-2} with 150 mm of moisture to 600 spikes m^{-2} with 750 mm of moisture.

The optimum seeding depth of wheat in moist soils is 2–5 cm. That depth gives adequate coverage with soil for germination and promotes vigorous roots and shoots. Deeper seeding, down to 10–12 cm, may be needed to reach moist soil, but greater depths should be avoided, especially with semidwarf varieties because of their short coleoptile.

Row spacings for wheat vary from 10 to 40 cm depending, like the seeding rate, on available moisture. Narrow spacings approach the ideal equidistant

spacing for minimum interplant competition and are used when soil moisture is ample. They are often combined with tram lines, i.e., unplanted rows for equipment travel, in intensive management systems. Wide rows are used for low moisture conditions, no-till planting, and intercropping systems.

Plants typically have more spikes and kernels and produce higher yields in east–west rows than in north–south rows. Orientation of rows perpendicular to prevailing winds apparently decreases plant stress and increases the harvest index.

Most wheat is planted with drills, air seeders, and disk seeders, and broadcasting is practiced in only a few areas. Broadcasting, or spreading the seed by hand, gives uneven distribution, poor coverage by soil, and favors weeds. Farmers in some areas, such as India, use the "desi" plow, which opens a furrow into which the seed is dropped by hand. Drills and seeders sow seed at the desired rate, spacing, and depth and cover it with soil. They range in size from three-row implements in China to equipment 10 m or longer in some areas. They are designed to make a furrow with a disk or hoe, deposit the seed, and cover it with a disk or chain. Larger drills apply fertilizer with the seed.

Fertilization

Most wheat is fertilized to provide nitrogen, phosphorus, potassium, and sometimes other nutrients. The grain contains 1.5–3% nitrogen and the plant utilizes only ~50% of the element from fertilizer, so 30–60 kg t^{-1} of grain is needed. Additional nitrogen, ~30 kg t^{-1} of forage, is required if the wheat is grazed. Phosphorus is present at 3–5 kg t^{-1} of grain, and only ~20% of the nutrient is utilized from fertilizer the first year. Recommended levels range from 16 mg per kg of acid soil to 50 mg kg^{-1} of calcareous soil. Potassium content of grain is low, but the element is critical for growth of vegetation. About 150 mg K per kg of soil is adequate. Sulfur, magnesium, iron, copper, and zinc also should be supplied if deficiency symptoms or soil tests indicate that a response is likely. Lime to bring the soil pH above 5.5 and prevent aluminum toxicity may be needed, particularly after long, continuous applications of nitrogen fertilizer.

Pest Control and Plant Growth Regulation

Weeds are controlled by planting weed-free seed, cultural practices, chemical herbicides, and hand harvesting. A dense, even stand of wheat is an excellent competitor with most weeds. However, sparse or uneven stands and some modern practices such as using semidwarf varieties and high rates of nitrogen fertilizer may allow weed populations to increase. Fallowing or succeeding wheat with other crops gives opportunities to control weeds mechanically during alternate years. Working the soil before planting wheat and, in some cases, adjusting the time and depth of seeding are effective. Different herbicides can be applied before or after planting to reduce many weeds. Removing weeds by hand, while laborious, may give them some value as food or feed.

Genetic resistance controls many diseases, particularly some rusts and viruses, most economically. Cultural practices can be used to alleviate many diseases, and fungicides are available for others. Seed should be free of pathogens or treated for common bunt, loose smut, and *Fusarium* head blight. Eliminating volunteer wheat plants can exclude some disease vectors. Covering residue of the previous wheat crop helps to reduce the incidence of tan spot and septoria. A firm seedbed decreases crown and root rots, and delaying planting may avoid diseases transmitted by aphids and mites. Fungicides effectively control powdery mildew and rusts but, because of their cost, are usually only recommended when the potential yield is high.

Insects, like diseases, are controlled by genetic, cultural, and chemical methods. Varieties are available with resistance to aphids, Hessian fly, and some mites. Cultural methods include rotations with other crops, removal of volunteer plants and crop residue, plowing to bury the insects, delaying planting, and accelerating harvest. Insecticides are effective against many pests but are often considered a last resort because of their cost.

Plant growth regulators are applied to wheat to deter lodging. Semidwarf varieties are much less prone to lodging than tall varieties and usually do not benefit from plant growth regulators. However, under the intensive management practices of high plant densities and high nitrogen fertilizer in western Europe and New Zealand, even semidwarf varieties may lodge. Plant growth regulators act by shortening the plants and strengthening their stems.

Irrigation

Many countries cannot produce wheat without irrigation because of arid conditions. Irrigation water is supplied from sprinklers, furrows, and basins. Center pivot sprinklers, which rotate about a fixed point, and tow line/sideroll sprinklers are popular because of their efficiency and low labor requirement. Other systems such as hand-move irrigators are declining because of their high labor demands. Furrows in fields typically run parallel to several rows of wheat, which may be on raised soil beds, and are supplied with water from pipes or canals. The system is versatile but often gives poor distribution of water, is labor

intensive, and complicates harvest. Basin irrigation involves flooding fields enclosed by levees and is well-suited to rice–wheat rotations. The system is efficient and gives good distribution, but initial costs are high and mechanical harvest may be difficult.

Irrigation of wheat is scheduled by two methods: depletion of soil moisture to a set level or by growth stage of the plants. Wheat utilizes ~50% of the available soil moisture before yield is reduced by stress, and irrigation is applied when moisture reaches that level. Alternatively, irrigation is scheduled at critical growth stages, such as germination, booting/heading, and early grain development, when moisture deficiency is most damaging to yield.

Harvest

Much of the world's wheat is harvested by hand with serrated sickles, particularly in Asia. The scythe, sometimes with a cradle to catch the plants, has replaced the sickle in some regions. Threshing to remove the grain from the straw is accomplished through trampling by livestock; stone rollers; tractors, sometimes pulling a disk or other implement; or small machines. The grain and straw are usually separated by tossing them into the air in a breeze.

Mechanical harvesters, called binders, that cut the wheat and tie it into a bundle were once widely used but are now found in only a few areas. The bundles are arranged in stacks known as shocks for the grain to dry and are then threshed by machines called separators.

Many large farms in developing countries and most commercial farms in developed countries use combine harvesters. These machines cut the plants and remove the grain from the straw and separate them in a single pass 1–10 m wide. Usually, only the spike and part of the stem are cut to minimize the amount of straw that goes through the harvester and to leave a stubble to protect the soil. Some combine harvesters, known as strippers, remove only the spike.

Wheat is usually harvested when the grain contains less than 14% moisture and can be stored without deteriorating. In some areas, such as the northern US and Canada, wheat is cut when the grain contains as much as 35% moisture and placed in windrows to dry, a process called swathing, before it is combine-harvested. In other regions, such as northern Europe and Hokkaido, the main wheat-growing island of Japan, the grain is combine-harvested when it contains 40% moisture and artificially dried. In those areas, the climate either does not permit the grain to dry naturally or causes the grain to sprout in the spike if it dries.

Wheat Agronomy in Major Regions

Asia

Asia is the world's major wheat production area with China and India leading production. Another important wheat-producing country is Pakistan (Table 2). Spring wheat predominates in China, with soft and medium-hard red varieties planted in autumn throughout most of the southern provinces and hard and medium-hard red varieties planted in spring across the north. Hard and medium-hard white winter and facultative wheat occupy most of the North China Plains. Over 90% of the grain is used for noodles and steamed bread.

Cultivation of wheat is labor intensive on small plots that are often part of large fields. In the major provinces of Henan and Shandong, wheat is mostly seeded with three-row drills pulled by draft animals. Other crops – rapeseed, maize, and vegetables – are often interplanted between the wheat plots. High amounts of chemical fertilizers are applied (Table 2), and additional nutrients are commonly supplied as compost. Over 50% of the wheat area is irrigated, usually from wells and reservoirs. Much of the irrigated wheat is rotated with rice for two crops each year. Harvest begins in May in southern regions, in June in the North China Plain, and in July and August in northern areas. Most of the wheat is harvested with hand sickles and threshed with animals or small machines.

Leaf, stem, and stripe rusts; powdery mildew; common bunt; and *Fusarium* head blight are usual diseases in China. Aphids and armyworms are common insects. Few pesticides, mostly fungicides, are used, and weeds are usually controlled manually and fed to livestock. Drought occurs with some frequency, and declining water tables and competition for other uses may limit availability of water for agriculture in the

Table 2 Agronomic practices for production of wheat in major countries in Asia

Practice[a,b]	*China*	*India*	*Pakistan*

[a] See Table 1.
[b] Fertilizer data from Fertilizer Use by Crop (1999) International Fertilizer Association, International Fertilizer Development Center, and Food and Agriculture Organization of the United Nations, Rome.

future. Hot, dry winds sometimes severely damage maturing wheat, and prevalent late spring and early summer rains occasionally cause severe preharvest sprouting.

India's major wheat region is the Indo-Gangetic plain, particularly the states of Uttar Pradesh and Bihar in the northeast and Punjab and Haryana in the northwest. Semihard and hard red and white spring wheat planted during autumn as the "rabi," or winter crop, predominate. The wheat is often intercropped with mustard, gram, and lentil and grown in rotation with rice, maize, sorghum, and pearl millet as the "kharif" (summer) crop. Only a little durum is produced, primarily under dryland conditions in the central and western areas. Grain is harvested in March and April in the northeast and late May and June in the northwest. Most of it is used for chapatis.

Drought, high temperature, occasional freezes, diseases, insects, and nematodes are problems on wheat in India. Dryland yields are low because they often depend on residual moisture from monsoons, and irrigated wheat is threatened by declining water tables and soil salinization in some regions. High temperatures hinder crop development and promote pests during autumn and restrict grain-filling during spring. Rusts, powdery mildew, and root rots are common under the high-yield management for most of the crop. Shoot fly, armyworms, and caterpillars are occasionally damaging.

The major wheat area of Pakistan is Punjab Province with over two-thirds of the total production taking place here. Wheat is the country's primary food, providing ~72% of the calories and protein, mainly as chapati and "nan." Only spring wheat, either hard or semihard, is grown, and white or amber varieties are preferred.

Wheat is grown as the rabi crop in rotation with cotton, rice, maize, sugarcane, and groundnuts. The soil is worked extensively and nearly pulverized between crops, and wheat is planted by broadcasting or drilling the seed during October and November. Prompt seeding is essential to avoid stress during maturation of the crop. Use of fertilizer, while fairly heavy, is probably inadequate for the potential yields (Table 2). Most of the wheat, over 88% in Punjab, is irrigated, primarily from canals, but the water supply is sometimes inadequate and saline. Harvest begins with the dryland crop in April and ends with the irrigated crop in early June. Most of the wheat is cut with sickles and threshed by animals.

Irregular availability of water, low rainfall, and high temperatures hinder wheat production in Pakistan. Considerable areas have become too saline for crops. Several weed species, leaf and stripe rust, and loose smut are serious pests.

North America

Canada is the sixth leading producer and second most important exporter of wheat (Table 3). The Prairie Provinces of Alberta, Saskatchewan, and Manitoba, the major area, grow mostly hard red spring wheat. Soft red and white winter wheat, which constitute ~5% of the crop, are mostly grown in Ontario. Soft white spring wheat is produced in the same provinces as hard red spring wheat. Durum accounts for 15–25% of the wheat area and is mostly raised in southern Saskatchewan.

Wheat farms in Canada are large and highly mechanized. Low temperature and sparse precipitation dictate many of the agronomic practices. Most of the wheat is grown as a crop-fallow rotation or a continuous monoculture, but rotations with rapeseed and other crops are increasing. Spring wheat and durum are planted as soon as fields can be worked during spring, usually in April and May. Winter wheat is planted from late August through September, preferably directly into the stubble of the previous crop or a thin stand of rapeseed or flax to trap snow to insulate the plants from cold. Moderate amounts of fertilizer are used in keeping with yield expectations (Table 3). Leaf and stem rust, *Fusarium* head blight, Hessian fly, midge, and wild oat and other weeds are problems. Along with drought, heat, late frosts, and preharvest sprouting sometimes hurt the yield and quality of the grain.

Harvest of wheat in Canada begins in August and continues into October. The grain is marketed through the Canadian Wheat Board; over 70% of it is exported.

The United States is the world's third largest producer and leading exporter of wheat (Table 3). The main classes are hard red winter wheat in the southern and central Great Plains, hard red spring wheat in the northern Great Plains, soft red winter wheat in the Midwest and Southeast, white wheat in the Northeast and Pacific Northwest, and durum in the northern Great Plains and desert Southwest.

Table 3 Agronomic practices for production of wheat in major countries in North America

K fertilizer ($kg\ ha^{-1}$)	4.2	24.3	0

[a,b] See footnotes to Tables 1 and 2.

Rotations for wheat depend mostly on moisture conditions. In areas that receive 350–500 mm precipitation, primarily the High Plains and Pacific Northwest, much of the wheat is alternated with summer fallow. Areas that receive 500–700 mm precipitation often follow a wheat–summer crop (sorghum, soybean, or sunflower)–fallow rotation or plant wheat every year. Higher levels of precipitation permit conventional rotations of wheat and other crops on alternate years or double cropping (two crops per year) with wheat as the winter crop and soybean, sorghum, or rice as the summer crop.

Winter wheat is seeded from late August in the northern Plains to early November in the South, and spring wheat from late autumn in the western US to early May in the North. Medium levels of fertilizer are used in most regions (Table 3). Only ~5% of the crop is irrigated. Leaf and stem rusts, several viruses, and *Fusarium* head blight are major diseases. Problem weeds differ among regions and are controlled with cultivation and herbicides. Hessian fly, greenbug, stem sawfly, army cutworm, and grasshoppers are troublesome insects. Harvest begins in southern states in May and progresses northward into September. About half of the grain is exported.

Wheat in Mexico is nearly equally divided between semihard or hard spring bread types and durum (Table 3). The northwestern states of Sonora and Sinaloa, which mainly grow durum, are the most important producers, followed by the Bajio and other parts of the Central Plateau. The grain is used for breads, pasta, and tortillas.

Most wheat is planted from October to December on land that is cropped with soybean, sesame, and other species during summer. Irrigation, usually from reservoirs, is needed to establish and maintain the crop until it matures because of the arid conditions. Large amounts of nitrogen fertilizers are used, reflecting the high yield potential (Table 3). Leaf, stem, and stripe rusts; septoria; and karnal bunt are common diseases. Several aphid species and cutworms occasionally damage the crop. The wheat is harvested from April to June; all of it is consumed domestically.

South America

Argentina is the twelfth largest producer and fifth largest exporter of wheat (Table 4). The Pampas provinces of Buenos Aires, Cordoba, and Santa Fe produce most of the grain. Hard red spring wheat is the major class; durum occupies less than 1% of the crop. Wheat consumption per capita is the highest in South America, primarily for artisan breads, pasta, and cookies. About 70% of the crop is exported.

Most wheat is grown in rotation with soybean, sunflower, and maize in mixed crop-livestock systems. The climate is generally favorable for wheat; however, variable precipitation and extreme temperatures sometimes limit yields. Soils are productive, but nitrogen and phosphorus are deficient in some areas. Wheat is planted from June through August. Moderate amounts of fertilizers are used, but few pesticides are applied to wheat (Table 4). Rusts, *Fusarium* head blight, take-all, septoria, and yellow spot are common diseases, reducing yields to ~10%. Aphids and other insects are occasional problems. The grain is harvested from November to January.

Over 90% of wheat production in Brazil comes from the states of Parana and Rio Grande do Sul. All of the wheat is spring type, mostly soft to semihard, for bread (Table 4). The crop meets only one-third of the country's needs, and the balance is imported.

Wheat is mostly grown in Brazil as a winter crop in rotation with maize or soybean. It is planted from April to mid-June, often as a cover crop. Yields are low because the climate and soils are particularly unfavorable for wheat (Table 4). Rusts, *Fusarium* head blight, septoria, and mildew are often epidemic. Soil acidity causes toxicity from aluminum and fixes phosphorus. Frosts periodically damage the crop at vulnerable stages. Rainfall is sometimes inadequate but more often excessive, causing floods and promoting fungal diseases during harvest from September to November.

Oceania

Australia and New Zealand, the two major wheat countries in Oceania, present contrasting examples of varieties, technologies, and yields. Australia is one of the world's leading wheat producers and exports over 80% of the grain (Table 5). The country's Wheat Belt extends across the states of Western Australia, South Australia, Victoria, New South

Wales, and Queensland. All the varieties are white spring types, which are usually planted during the autumn months of May and June. Six classes of wheat are produced, the most important being prime hard, hard, and standard white and durum. Output of wheat is steadily increasing as former sheep areas are cultivated and the yield potential of new varieties increases.

Production of wheat in Australia is constrained by availability of moisture, since much of the country is arid or semiarid and only 8% of the crop is irrigated. Farms are large and heavily mechanized. Fertilizer use is low because of the generally low yield potential (Table 5). Diseases – leaf, stem, and stripe rusts; crown rot, and yellow spot – are frequent problems. Late frosts sometimes damage plants from the pre-flowering to early grain-filling stages. Salinity from rising water tables is becoming troublesome, particularly in Western Australia. Preharvest sprouting caused by persistent rains after the white grain ripens is a major concern. The grain is harvested during October through December.

New Zealand grows wheat primarily along the eastern coastline areas of Canterbury, North Otago, and the lower North Island. Fields are generally small, ~10 ha, but the crop is managed intensively and yields are high (Table 5). About two-thirds of the varieties are facultative types that are sown in autumn (May), and the balance are spring varieties that are planted in late August to early September. Some 60% of the grain is used for bread products and 40% for livestock feed.

P fertilizer (kg ha^{-1})	12.4	10.9
K fertilizer (kg ha^{-1})	0.2	8.3

[a,b] See footnotes to Tables 1 and 2.

Most wheat in New Zealand is grown under contracts that impose strict criteria for quality and pesticide residues. High rates of nitrogen fertilizer are often split into several applications during the growing season, as are fungicides to control foliar diseases (Table 5). Much of the wheat is irrigated. Growth regulators are used to prevent lodging of the plants. The favorable conditions and intensive management commonly result in yields of 10 t ha^{-1} or higher, particularly of feed wheat. Harvest begins in early January and continues into late February. Most of the grain is artificially dried.

Eastern Europe and Western Asia

Wheat is the major cereal in the Russian Federation, the fifth largest producer in the world (Table 6). Southern Russia, including the North Caucasus, Southern Black Soils area, and Volga Valley, is the primary winter wheat region. The Don Basin, middle Volga, and southwestern Siberia grow most of the spring wheat, both bread types and durum. Winter and spring bread wheat are used for various baked products, which are important in the population's diet, and for livestock feed. Durum is used for bread as well as pasta.

Small private farms and large joint-stock farms produce wheat in Russia. Both are heavily dependent on mechanization, but economic difficulties cause much of the equipment to be obsolete and production inputs to be low. In addition, variation in weather among regions and years greatly affects production. Nevertheless, the reorganization of former state-owned farms has increased efficiency and contributed to excellent harvests during recent years (Table 6).

na = not available.

Winter wheat is planted in September and October following rotations of continuous wheat or other cereals, legumes, or flax. Winterkilling from severe cold sometimes necessitates replanting with spring wheat. Most spring wheat is sown during April and May. Use of fertilizer, while low, is increasing, but few other chemicals are applied to wheat (Table 6). Leaf rust, powdery mildew, snow mold, *Fusarium*, and aphids are major problems in addition to drought and winterkilling. Harvest begins in July in southern regions and extends into autumn in northern spring wheat areas, where it is sometimes disrupted by winter weather. The grain is presently sold to a state fund.

Kazakhstan produces both winter and spring wheat, principally on the northcentral Steppes around Kostana. Most of the crop is grown on large cooperative and joint-stock farms. Winter wheat is planted in September and October and spring wheat is planted in April and May. Drought occurs about 2 years of every five and use of fertilizer is declining, causing yields to be low (Table 6). Other problems stem from inadequate equipment, poor infrastructure, and an undeveloped market system. Harvest in the major area begins in August and continues into October.

The principal wheat area of Ukraine is in the eastern and southern parts of the country. Over 90% of the crop is hard winter wheat, and 5–10% is durum (Table 6). Most production takes place on large private associations that reformed from state and collective farms. Although Ukraine is a traditional exporter, most of the grain is consumed locally as breads or fed to livestock.

Most Ukrainian wheat is planted in September. Fertilizer use is low because credit is difficult, and other chemicals are expensive (Table 6). Little of the wheat is irrigated, and drought can occur anytime during the season. Leaf rust, powdery mildew, and septoria are often problems. Harvest during July and August can be complicated by inadequate equipment and adverse weather.

Turkey produces winter bread wheat, the major class with 50% of the area, on the Anatolian Plateau and Thrace Province (Table 6). Spring bread wheat and durum, each ~20% of the area, are mostly grown near coastal areas. The balance of the wheat is winter durum. Wheat on the Anatolian Plateau is usually alternated with fallow. It is planted during October, as is spring wheat on the coast. Medium amounts of fertilizer and other chemicals, primarily herbicides, are used (Table 6). Little of the wheat is irrigated and yields vary greatly with precipitation, which averages only 200–450 mm on the Anatolian Plateau. Moderate to severe drought every 2–4 years, yellow rust, leaf rust, root rot, and tan spot are major problems. Harvest is during June and July.

Iran grows nearly equal areas of spring and winter bread wheat (Table 6). The crop occupies over half of the arable land in the country, and consumption of wheat foods is among the highest in the world. Lavash, sangak, and other flatbreads; biscuits; and noodles are important products.

Precipitation varies widely across Iran and averages ~250 mm annually. Only about one-third of the wheat is irrigated, but it provides one-half to two-thirds of the crop. Much of the irrigated wheat is in eastern and southern provinces, and dryland wheat is predominately in western and northwestern provinces. The crop is planted during October and November. Moderate amounts of fertilizer are used (Table 6). Harvest begins in the southern and eastern areas in mid-April and ends in northern areas in August.

Western Europe

France, like the other countries of western Europe, has a climate that is conducive to high yields of wheat (Table 7). The crop is managed intensively with high levels of inputs. The country is the major producer in the region and ranks fourth in the world. The primary wheat area is the northern half of the country, with Centre and Picardie the leading provinces. The major class is soft winter wheat, but some soft spring wheat and durum are also produced. Most of the grain is consumed as bread, and variable amounts are fed to livestock depending on the cost relative to other cereals.

Wheat is planted during October and November using high seeding rates, narrow rows, and tram lines. High rates of fertilizers and pesticides are applied, usually several times during the growing season (Table 7). Stripe rust, leaf rust, powdery mildew, and septoria are common. Harvest is in July and August.

Production of wheat in Germany differs substantially between the former east and west sectors. The former east sector has large farms formed from state cooperatives after reunification. Inputs and yields,

Table 7 Agronomic practices for production of wheat in major countries of western Europe

Practice[a,b]	*France*	*Germany*	*United Kingdom*

[a,b] See footnotes to Tables 1 and 2.

while low relative to the west, are increasing (**Table 7**). Western farms, in comparison, are small but cultivate wheat intensively. Bayern and Niedersachsen are the major wheat states. Most varieties are semihard to hard winter wheat that are consumed as mixed bread with rye, whole wheat bread, and white bread. Considerable quantities are also fed to livestock and exported each year.

Most wheat is produced on mixed crop/livestock farms in Germany. Usual rotations with wheat include other cereals, various legumes, rapeseed, and sugarbeet. Wheat is mostly planted during October and, like in France, rates of seeding and application of fertilizer and other chemicals are high (**Table 7**). Rusts, powdery mildew, and septoria are major diseases. Harvest during July and August is sometimes disrupted by adverse weather, which affects both the yield and quality of grain.

Wheat is grown in the United Kingdom as far north as Scotland, but it is concentrated in southeastern England and the Midlands. Yields are extremely high because of the favorable climate and intensive management (**Table 7**). Soft and semihard winter and spring classes that are used for breads, biscuits, and pastries are grown. Much of the grain is also fed to livestock and exported.

Most wheat is grown on mixed crop/livestock farms in rotation with forages and other crops. The grain is usually planted during October and November, but sowing can be as late as January depending on the rotation and the weather. High seeding rates, narrow rows, and tram lines are used and heavy rates of fertilizer are applied (**Table 7**). Nitrogen fertilizer is often split among four or five treatments, and fungicides to control foliar diseases and growth regulators to prevent lodging are common. Little of the wheat is irrigated. Yellow rust, leaf rust, eyespot, tanspot, powdery mildew, and fusarium head blight are serious diseases. The grain is harvested during July and August.

Harvesting, Transport, and Storage

S T Grundas, Institute of Agrophysics, Lublin, Poland
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The harvesting, transport, and storage of wheat is big business worldwide because of the enormous size of

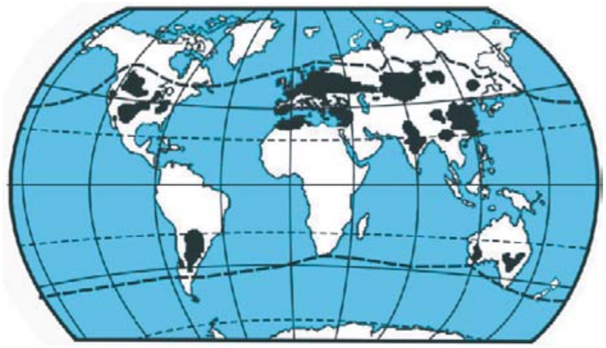

Figure 1 The main wheat-growing regions in the world; the northern and southern distribution boundaries are marked with broken lines. (Reproduced with permission from Grzesiuk S and Kulka K (1988) *Biology of Cereal Kernels*. Warsaw: Polish Scientific Ed. (in Polish).)

Figure 2 Combine harvesting of wheat. This equipment cuts off the wheat stalks, threshes the grain from the reaped heads, and winnows away the chaff, depositing the grain in a bin. The grain is later transferred by auger (protruding above the combine to the left), into a truck driven beside the combine while it continues to harvest.

the global wheat-growing industry. Wheat cultivation covers a total of ~240 million hectares (Mha) around the world. Most of this (~90%) is occupied by bread wheat (*Triticum aestivum*), which represents the greatest number of crop-yielding varieties of starchy grains. The numerous varieties of durum wheat (*T. turgidum* ssp. *durum*) are cultivated on the remaining area.

The geography of wheat cultivation is illustrated in Figure 1. The greater areas of wheat cultivation are in the northern hemisphere. Wheat is grown both as a winter and as a spring cereal in the moderate climate zones, and in the tropical regions in low lands and uplands alike. The distribution of wheat over the various parts of the world is related to the numerous species and varieties, and to their adaptability to particular environments. Wheat harvesting is a continuous process around the world and every month is a period of harvest in one of the wheat-growing regions.

Historical Perspective

Wheat harvesting is a three-stage process – reaping, threshing, and winnowing. The first step of reaping involves cutting off the stalks of the wheat plant after it has become dry and ready for harvest. Before recent times of mechanization, reaping was performed by hand. The stalks were cut with a scythe or with a sickle, having a curved hook-like blade. The cut stalks were often left in the field in standing bundles with the heads uppermost, allowing the heads to dry out more, if this were necessary.

These bundles have been called shocks, stooks, or ricks. Mechanization led to the possibility that this step of cutting could be performed by machines, leaving the cut stalks lying in lines (swaths) if they needed to be allowed to dry more before threshing. "Swathing" is still performed in climates where harvesting is likely to be done under moist or even snowy conditions, the lying stalks being left to dry ready for the next stage of harvest.

Threshing involves removing the grain (with husks) from the stalks. Traditionally, this meant vigorous beating to separate the grain in the head from the rest of the plant parts, followed by winnowing, to free the grain from the husks, plus using some means to blow away the chaff.

Significant among the many inventions to mechanize harvesting was the reaper conceived by the American inventor and manufacturer, C. H. McCormick (1809–84). His reaper, patented in 1834, revolutionized wheat production. He went on to organize the manufacture of farm machinery on a mass-production basis. His success helped to speed up the large-scale mechanization of American agriculture. Later developments brought the modern combine harvester, which combines the three major operations of reaping, threshing, and winnowing in one machine (Figure 2).

By way of contrast, recent methods of harvesting are designed to map the harvested area according to the yield throughout the harvested area. This is done by fitting geo-positioning system (GPS) equipment to the combine. In this way, the position of the combine in the field is known at any time. The yield per unit area is recorded continuously, providing a map of grain yield throughout the field. The technique, known as "precision agriculture," is designed to identify the parts of the field that are under-producing, so that attempts may be made to remedy the problems.

This may involve taking soil samples to test for mineral deficiencies or checking for possible waterlogging in these patches of ground.

Destinations for the Harvested Grain

Historically, grain has been grown to meet the needs of the farming family, the grain being stored on the farm to provide food until the next harvest. This type of subsistence farming is still a way of life in some regions. As specialization of occupations developed, the farmer also produced grain for sale to neighbors and in nearby markets. Trade in wheat has now extended to see the movement of vast amounts of grain internationally. Furthermore, the sophistication of international trade has required that grain-quality specifications are suited to the types of process and product appropriate to each market. For example, many types of bread manufacture require hard-grained wheat that mills well to produce strong-dough properties, whereas, soft wheat giving extensible dough is required for cookie and cake production. Further specifications are required for many other products made from wheat, such as Arabic breads of many types, various kinds of noodles, pasta products, and feed grain for animals.

Many of the major wheat-growing countries produce much more wheat than can be consumed domestically. They, therefore, export a considerable proportion of their production. In doing so, they seek to maximize the returns for their grain on the international market, whilst focusing on markets that offer advantages for transport costs. The marketing organizations of the wheat-exporting countries have had to conduct extensive market research to determine what quality attributes are appropriate to targeted market destination, particularly depending on the types of products made and processing used in these regions. As a result of this knowledge, breeders have selected varieties that suit these needs, and specific varieties have been recommended for growth in appropriate regions. A range of other quality considerations must also be assessed, to ensure that the quality requirements of the specific markets are met.

Meeting Appropriate Grain-Quality Standards

The range of quality requirements depends on the relative influences of genotype (the variety sown) and the effects of growth conditions, as indicated in Table 1. For example, the moisture content of the grain after harvest is solely dependent on harvest conditions and farm management, and the variety originally sown is not at all relevant. Moisture content is an important determinant of quality during storage, because moist grain is more susceptible than dry grain (e.g., below 12% or 13% moisture) to fungal attack and insect infestation. Similar considerations hold for the presence of weed seeds and pesticide residues, these quality factors also being wholly determined by growth and harvest conditions (Table 1).

Table 1 Grain-quality attributes for wheat, listed according to the relative influences of genotype and growth environment on each attribute

Quality attribute	*Influence of genotype (variety)*	*Influence of growth conditions*
Variety	Sole	Nil
Starch properties	Major	Minor
Milling quality	Major	Minor
Grain hardness	Major	Minor
Protein content	Significant	Significant
Protein quality	Significant	Significant
Dough characteristics	Significant	Significant
Preharvest sprouting	Significant	Major
Defects	Minor	Major
Test weight	Minor	Major
Moisture content	Nil	Sole
Pesticide residues	Nil	Sole
Contaminants	Nil	Sole

Adapted from Wrigley CW and Batey IL (2003) Assessing grain quality. In: Cauvain SP (ed.) *Bread Making: Improving Quality*, pp. 71–96. Cambridge: Woodhead Publishing.

On the other hand, aspects of grain quality such as hardness and milling quality are largely determined by the variety involved. Genotype has considerable influence on the protein content and dough properties, but so too do the growth conditions, including such factors as the level of nitrogen fertilizer and the presence or absence of frost, drought, or heat stress. For these reasons, many grades of wheat with particular quality requirements have specifications for a selection of specific varieties of similar quality, suited to the growth conditions expected for the region. Although variety is an important factor affecting quality, wheats are seldom classified on the basis of a single variety. Thus, each class consists of a group of varieties of similar characteristics for specific purposes.

The testing of a truck-load of grain for quality (Table 1) is ideally performed on delivery to a flour mill or storage terminal (elevator or silo). These tests must generally be performed within a short time, probably several minutes. This is because a decision must be made, while the truck is waiting, on where the grain should be tipped. In such situations, there are generally several storage cells, each holding a different

Figure 3 Delivery of harvested grain to a storage terminal may involve first stopping the truck-load at a sampling stand, so that samples of grain can be taken to assess its quality.

grade (class) of wheat, each grade being suited for distinct uses with different quality specifications.

The first step is usually to take samples from the truck's load for the tests to be carried out. Samples may be taken with a hydraulic set of probes, which are lowered into the load of grain. Alternatively, sampling may be performed manually with a spear probe, such as is shown in Figure 3. This spear consists of two long concentric cylinders, each with vertical slits. When inserted, the slits are closed. After insertion, the top of the spear is twisted, to open the slits allowing grain to flow into the inner tube from all levels of the grain load. In the case of manual sampling, an operator thrusts the spear into the grain after climbing on top of the load, or leaning over from an elevated sampling stand. Spear samples are taken at several specified points across the load, with the aim of obtaining a combined sample that is representative of the whole load. Refer to the web site of the United States Department of Agriculture (www.usda.gov/gipsa/pubs/farm-proc/practical_proc.htm) for standard sampling procedures.

Testing to Ensure Grain-Quality Standards

The grading of wheat grain involves the segregation and valuation of grain consignments based on the physical and chemical properties of the grain. The scope of wheat-grain grading is related to our current agricultural knowledge, as well as to the level of organization of the local cereal market (pricing policies, grain-purchasing systems).

The systems of wheat grain grading include the following groups of grain properties:

1. "Stable" properties, related to genetic properties (determined by the variety), such as grain hardness, size, shape, and color (red or white). These are the factors towards the top of the list in Table 1, distinguished by being only slightly influenced by growth conditions. These quality attributes have been "built in" as a result of intentional breeding and selection. (*See* articles on **Wheat**: Genetics; Breeding.) Testing for these mainly involves varietal identification.
2. "Variable" properties, subject to change as a result of drying, cleaning, sorting, and transport (moisture content, contamination, damage to grain), related to climatic conditions, and management practices (e.g., bulk density). These factors, appearing lower down the list in Table 1, are described in detail in articles on **Cereals**: Grain Defects; Grain Diseases, and **Contaminants of Grain**. Specific testing must be conducted for each of these.
3. "Permanent" faults and defects, such as stale smell, fermented smell, foreign smell, or faults that can be rectified, e.g., washing grain contaminated with soil or foreign matter.

The "stable" properties provide a primary basis to determine the appropriate market class. They are, thus, critical for grade determination in international trading. As they are mainly determined by genotype, this is the reason for specific varieties to be nominated for premium grades and classes.

Grain hardness, a "stable" property, is an important basis for classification in trade. In relation to grading, the following definitions are applied:

1. Hard wheat is wheat, which, as a result of variety and breeding in combination with environmental factors during growth, has a vitreous endosperm generally considered an advantage for the production of bread-making flours.
2. Soft wheat is wheat, which, as a result of variety and breeding, in combination with environmental factors during growth, has a white opaque endosperm generally considered more suitable for the production of cake and biscuit flours.

The "variable" properties are secondary properties, although also important from the viewpoint of grain quality. The group of variable properties, systematized into several ranges in terms of values, constitutes grain grades, which are identical for many of the market classes. The quality grading of wheat grain sometimes includes an assessment of mechanical damage, which occurs wherever grain is subjected to the destructive action of internal or external forces.

The results of research carried out using X-ray methods have shown significant differences in grain endosperm cracks between common wheat varieties. Natural wetting of dry grain (below 15% moisture) during rainfall in field conditions is one of the main reasons for cracking. Considering the results of endosperm cracks, which can appear before harvest in some climatic regions of wheat production, special attention should be paid to this potential defect, and to the susceptibility of specific varieties to this fault.

The susceptibility of wheat to mechanical damage is determined by genetic factors (hard and soft grains), environmental effects (climatic conditions during the preharvest period), and by the conditions of grain storage (excessive humidity). The combination and selection of these properties determine further aspects of grain quality. Some of the "permanent" faults and defects are a basis for excluding shipments during grain grading, as their character is likely to disqualify grain from food use. Defined faults, which can be rectified, may make some grain lots eligible for special grades of defective quality.

Quality Specifications of Individual Countries

Standards of wheat quality have been established by most wheat-growing countries. Canada and USA, as examples, have systems of wheat grading with classes based on the varietal properties expressed in the vegetation period (spring versus winter wheats), grain coloring (red or white), and hardness (hard or soft). Within the various classes, there are specific grades (subclasses) each with their distinctive quality specifications, often relating to protein content. Five classes of wheat are distinguished in USA: Hard and Soft Red Winter, Hard Red Spring, Durum, and White (subclassified into Hard and Soft Winter White and Hard and Soft Spring White). Wheat grading in the USA additionally provides, in the subclasses, for the proportion of vitreous grains.

Groups of varieties of appropriate quality are specified for most grades of wheat. As an example, in Canada the model Hard Red Spring wheat was originally the variety Marquis. Many years ago, it was replaced successively by varieties that are genetically similar with respect to their genetic potential for appropriate grain quality, but of more value economically with respect to yield potential and disease resistance. More recent replacements include Thatcher, Manitou, and most recently, Neepawa – the "equal-to-or-better-than" variety for Canada Western Red Spring.

Canada Prairie Spring Red wheat is a medium-strength wheat suitable for the production of certain types of hearth breads, flat breads, steamed breads, and noodles. Canada Western Amber Durum specifies "any extra strong red spring wheat that is equal to or better than" the variety Hercules. In recent years, an extra class, "extra strong," has been added to the Canadian grading system, and it is made up of "any extra strong red spring wheat that is equal to or better than" the variety Glenlea. This is a good example of the use of a specific variety being used as the basis of a specific class. In this case, "extra strong" refers to the strength of the dough made from the flour, the extra-strong gluten of this class being attractive for special bread types and for blending with wheats with low and/or weak gluten content. Wheat is also produced in the eastern provinces of Canada, where the wheat is graded into various classes such as "Canada Eastern Soft White Spring" and "Canada Eastern Soft Red Winter."

In Argentina, most of wheat cultivation involves hard red winter wheat, also known as "Plate" wheat. Wheat growing is concentrated in the provinces of Buenos Aires, La Pampa, Cordoba, and Santa Fe. Argentina uses a system of bread-wheat division into subclasses based on grain hardness (hard, semi-hard, and soft). Export classes are named according to the ports of shipment (*see* **Grain Production and Consumption**: South America).

In Australia, the crop might be classed as spring wheat, because the conditions in all parts of the wheat belt do not provide the cold temperatures

needed for the vernalization of a winter wheat. Nevertheless, some varieties approach the winter-wheat type by having a long maturity period. A high proportion of the Australian wheat crop is exported (often ~80% of it), and it has been an important accent of marketing efforts to ensure that market requirements are understood and matched. Australia has developed a grading system based exclusively on white-grained wheats.

Prime Hard is the top-quality grade, with a protein content of 13–14%, high milling quality and processing attributes. Flour from it is used in export markets for high-protein yellow-alkaline noodles, Wanton dumpling skins, high-volume breads, flat breads, rotis, and chapatis. Its high protein content suits it to blending with lower protein wheats. Australian Hard (hard-grained varieties with a minimum protein content of 11.5%) suits European-style breads, Middle-Eastern flat breads, and Chinese steamed products such as Mantou and Pao. Premium White (minimum of 10% protein) is suitable for a wide range of products, including Hokkien, instant and fresh noodles, Middle-Eastern and Indian-style breads, and Chinese steamed bread.

Australian Standard White is a medium- to low-protein white wheat. Australian Soft Wheat (10–11% protein), a smaller part of the crop than the hard-wheat grades, is used for white-salted noodles in Japan and Korea, and for confectionary products, such as cakes, pastries, biscuits, cakes, steamed buns, and snack foods. The Australian Noodle grade is a premium class because its special starch properties make it ideal for white-salted udon noodles for the Japanese and South Korean markets. Grain that does not meet the specifications for the above grades is classed as General Purpose of Feed wheat. Australia also produces three grades of durum wheat.

In Europe, and especially in France and Germany, intensive agricultural procedures have resulted in virtually the highest grain yield per unit of area of cultivation. Traditionally, European countries have been importers of wheat, especially of strong wheats for blending, but since the 1970s, the European Community has been a significant wheat exporter. In recent years, "clubs" have been set up by wheat producers who achieve yields of 10–15 $t\,ha^{-1}$. In this region, the dominant types are wheats of the Soft Red Winter class. The European Union countries have dozens of high-yielding varieties of very good grain quality. In Mediterranean countries, such as Italy and Spain, durum wheats make significant contributions to wheat production.

East European countries grow mainly red winter wheats, some of which have very good baking qualities. In the countries of the Commonwealth of Independent States (CIS), both spring and winter, red and white wheats are grown, as well as some durum wheats. The CIS has the largest area of wheat cultivation in the world. The leading varieties, in terms of yield and grain quality, are the winter wheats, Bezostaya 1 and Mironovskaya 808, and the spring wheat Saratovskaya 29.

Wheat grading in the CIS is based on principles similar to those followed in the USA, with the distinction that classes are replaced in the CIS by types, and subclasses by subtypes, primarily designed to take into consideration the proportions of vitreous grains. Some European countries (e.g., France, Germany) use a grading system based on protein content, bulk density, and the sedimentation test. With only slight differences in the appearance of many varieties, and with the possibility of grain-quality reduction as a result of environmental effects, grades have been developed to include, in addition, the contamination of the grain and the Falling Number test for sprout damage.

Other countries, in which wheat is grown or only imported, also use specific standards for the evaluation of the quality of wheat grain and its products. Most frequently, such systems are modifications of those presented above.

Transportation of Grain

In many countries, the regions of grain production are distant from the centers of population and from the export terminals. Transportation is thus a significant expense. It is common for trucks to be used for delivering the grain from the farm to the country elevator (silo) or to the flour mill. This delivery point is the primary opportunity for testing the quality of the grain, so that best quality grain can be segregated from poorer grades. Truck delivery and sampling is illustrated in Figure 3. Country elevators are always situated near transport facilities, as is illustrated in Figures 3–6.

Rail transport is the usual means of transporting large volumes of export grain long distances from country elevators to the terminal elevators. These are generally located at harbors, ready for the loading of ships for transport by sea to importing countries. This form of transport is illustrated in Figure 7, but in this case, there will be another transfer of grain before it reaches its export destination. Figure 7 shows grain being loaded into a lake barge at Thunder Bay, Canada, for movement through the Great Lakes of North America to a further terminal where it will be transferred to a sea-going ship.

Much of the grain exported from the United States is carried by barge down the Mississippi and

Figure 4 Vertical silo storages in country Australia.

Figure 5 Circular silo, designed to hold different grades and types of grain in the separate vertical cells.

Columbia Rivers to export elevators, where it is unloaded and stored until it can be loaded onto ships. In addition, some grain is transferred directly from barge to ship, without being stored in an elevator. An export elevator can load a ship with 60 000 t of grain, worth over $10 million, in two days. The weight certificate must thus be very accurate, due to the large sums of money involved.

By contrast with subsistence farming, in which the family consumes the grain it produces, the process of moving export grain is complex. It passes through the following stages: from the farm, to country silos, possibly via regional centers, to terminal storage elevators. At every stage, grain is subjected to checking and classification. This ranges from highly detailed to more general grading. Treatment may include improvement (drying, cleaning, sorting, and disinfestation, if required), and grouping of supplies into larger batches of uniform quality. Isolated fractions of undersize grain and lower-grade wheat may be sold on the local market.

Storage

Like transport, grain storage is likely to start at the farm. Many years ago, wheat was bagged for transportation and storage, but bulk transport and storage is now usual, except in cases of special quality requirement. Some regions have a tradition that grain is delivered to a country elevator or mill immediately it is harvested, whereas in other places, on-farm storage is common. Retention of the grain at the farm may provide trading advantages for the

Figure 6 A horizontal storage silo (at right) and bunker storage (left and top center). Grain in the bunker storage is laid on layers of plastic sheet and also covered over with sheets of plastic. Note the freshly harvested field on the extreme right.

Figure 7 Loading of bulk wheat for export at Thunder Bay, Canada.

grower, permitting him to wait until prices rise before selling.

Nevertheless, most major wheat-producing countries have major storage facilities through the grain-growing regions. These may take various shapes and sizes, as shown in Figures 4–6. The vertical silos in Figure 4 are an older type, although these are being modernized by sealing them to permit insect disinfestation by fumigation, or preferably by treatment with carbon dioxide. Figure 6 shows a few forms of storage, conveniently situated beside rail and road transportation. The long, low structure at right of Figure 6 is known as a "horizontal storage." Like the vertical silos (Figures 4 and 5), it may have several separate cells to accommodate different grades and types of grain.

Stability during storage and transport are the great advantages of the grains as food sources. During storage, the rate of grain respiration is very low, and this accounts for its stability and the very low losses in the mass of the stored grain. However, these advantages depend on the condition of the grain, its moisture content, temperature, and soundness. Grain respiration may be more intense in soft grain than in hard grain. If grain moisture content is relatively low (below 14%), and if the bulk of grain of that moisture content is homogeneous, the grain can be stored for several years without significant losses. However, if proper air temperature and humidity conditions are not observed in the storage area, the increasing humidity resulting from the process of grain respiration may lead to the phenomenon of spontaneous heating of the grain, and this may render it unfit for human consumption.

In some wheat-growing regions, e.g., in the Scandinavian countries, wheat grain is harvested relatively moist and it must be dried to maintain its quality. Drying must be performed under controlled conditions of temperature and humidity. Exceeding the required temperature may lead to the loss in the baking value of the flour. To avoid damaging grain meant for baking purposes, its temperature should not exceed 35°C at moisture contents above 20%.

Future Prospects

Various revolutionary approaches to grain storage and transport have been proposed and tested. One of these is the possibility of pumping a slurry of grain in liquid through a pipeline. This system has worked well for minerals in some cases, but it has not yet been adapted to any significant extent for wheat grain. One difficulty is to choose an appropriate liquid medium. Rapeseed oil has been used in trials, but the difficulty has been to remove the oil efficiently. Another possibility is supercritical liquid carbon dioxide at low temperature and high pressure; this was found to extract lipid from the grain and to be very expensive.

It is likely that conventional methods of harvesting, storage, and transport will continue with relatively slow change. However, new approaches may be directed towards improving the quality of grain consignments. This may involve more controlled harvesting, by using "precision agriculture" to confine harvesting to parts of the field that have higher protein content, thereby achieving a premium for a significant part of the harvest that would not have otherwise been possible.

A proven approach to avoid downgrading due to sprout damage involves using an immunoassay to test grain from various locations in the field, thus to determine those parts of the field that are not damaged in this way. This information can then be used to confine the travel of the combine to the sound parts of the field, and thus avoid the risk of losing a premium payment by harvesting sprouted grain with the sound grain.

For storage, new approaches to preventing loss to insects and vertebrates is a priority, because significant losses of this nature continue as a major problem, especially in developing countries.

Grading and Segregation

R L Cracknell, AWB Limited, Melbourne, VIC, Australia
R M Williams, Curtin University, Perth, WA, Australia

Introduction

A key demand of flour millers and their customers is a consistent product. Unfortunately, the quality of wheat can be variable, not only between years but between shipments that depend on the medium of transport – be it an ocean vessel, a rail wagon, or a road truck. This variability is due to the effect of the environment on the inherent genetically determined quality factors, and can be traced back to quality variation within a single head of grain. Therefore, the delivery of a consistent product to customers is a considerable challenge to suppliers of wheat.

The terms grading, classification, and segregation can take on different meanings around the world, but in essence, they all describe processes that are designed to ensure that the parcel of wheat that is ultimately created meets the needs of discriminating buyers, performs in a predictable and consistent way, and, in the better developed systems, exhibits quality attributes that are ideal for the production of specific wheat-based foods. Examples are the hard red spring wheats produced in Canada and the United States that are well suited to the production of high-volume breads made by the traditional sponge-and-dough baking process, and the noodle wheats produced in Western Australia, which are well suited to the production of white salted noodles in Japan and Korea. A number of different approaches will be discussed in this article.

The Quality Feedback Chain

Before tackling the different approaches that are used around the world to ensure that customer quality requirements are met, it is important to first understand what we will call the quality feedback chain (Figure 1). Starting with the development process of a new wheat variety, it is assumed this will take somewhere between 8 and 15 years. New technologies now mean that the breeding component of variety development has been reduced, but there is still the need to bulk up seed crops, then there is the further delay due to the uptake of new cultivars by farmers. Depending on the attributes of the variety, the time frame of this adoption phase by farmers can vary considerably, but at least 2 years is required before significant tonnage of

seed is available for customers to use. Successful breeders have to anticipate the future quality requirements of customers not today, but in that 8–15 year period that will elapse, before their new variety is available for harvest and utilization.

Therefore, an important component of delivering a consistent product to customers is not only managing the year-to-year quality variation as a result of factors such as drought, harvest, rainfall, and/or frost, but having a product that meets processing needs, such as baking or noodle-making and eating performance. This requires an extensive working knowledge of customers' processing needs and working with them to enhance the product being delivered. An added complication in the international trade of wheat is that other suppliers are competing for a share of that customer's business. Therefore, not only do suppliers need to have ongoing quality improvement, but must also continually monitor the competitiveness of their products.

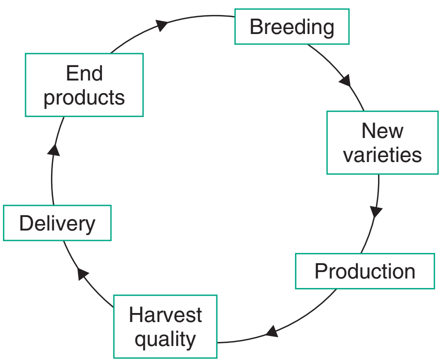

Figure 1 Wheat quality feedback chain.

Testing Grain Quality

As an example of the potential for the genetic-by-environment interaction, the annual harvest of wheat in Australia occurs in a 4 month period, commencing in Queensland in late September/early October, and finishing in the higher rainfall areas of NSW, Victoria, South and Western Australia in late December/early January. During this intense period of activity, each truckload of a 20–25 million ton (Mt) wheat harvest is sampled and quality tested when it is delivered to the silo network around the country. Given the large quantity of grain harvested (wheat comprising ~60% of total grain production), speed of testing is essential to minimize delays and to avoid harvest-weather damage. Quick and accurate tests exist for physical or environmental characteristics such as bulk density, protein level, and cleanliness. Industry-recognized receival standards are used to determine whether wheat is suitable for milling or feed purposes from a physical-quality perspective. However, for inherent or genotypically determined quality attributes, such as milling performance, dough properties, and end product qualities, such rapid tests are not yet readily available. Instead, Australian buyers and sellers of wheat rely on the statutory variety declarations by farmers at the time of delivery to characterize genotypic quality. The success of this approach relies solely on the classification of a variety's genetic quality characteristics before it is released for commercial production. Five countries have dominated world wheat trade over the last 5 years (Table 1) and these will be discussed with respect to how they strive to match the quality expectations of their customers.

Inherent Quality and Genotype Classification

Around the world, variations of the same theme are employed by buyers and sellers of wheat; i.e., the comparison of new varieties with existing varieties, whether they be targets or minimums, to determine what class or value the new variety should be given. However, the specifics of this matter vary – from the largely unregulated system which exists in the United States, to the formal process in Canada governed by both the Canada Grain Act and Seeds Act and Regulations, and the formal but more pragmatic and market-driven approach that is followed in Australia.

Australia

The major buyers (and hence classifiers of wheat) in Australia, AWB Limited and the domestic flour-milling industry have strict protocols in place to obtain a classification. These requirements focus on the provision of multiple years of quality data, from the various classification regions, for an extensive set of tests, the results of which are compared against control varieties, rather than empirical values. This recognizes the seasonal influences on wheat quality and that empirical values may vary from year to year. The classifiers also acknowledge that some parameters are essential and cannot be compromised, while less important attributes failing to reach the necessary levels can be counter-balanced by exemplary performance for other, more important quality attributes. This means that minor deficiencies do not necessarily have a negative influence on the final classification decision, provided they are compensated by other attributes.

In addition to establishing the dollar value, the classification of a variety is important because current technology does not allow for accurate assessment of the genetic attributes like milling performance, flour and dough properties, and end product suitability. Therefore, instead of performing tests at harvest, at the first point of delivery, a variety-declaration system is used in Australia. Farmers are required to make a statutory nomination of the variety being delivered, and this establishes the inherent quality profile and also the payment potential (technology allows quick and accurate measurement of physical attributes). The classes of Australian wheat are valued differently based on their quality, as illustrated in Table 2. As a consequence of this variety-declaration system, the classification process is extremely important in ensuring that the right quality is ultimately delivered to end users.

Canada

The Canadian variety-registration system is a formal, fee-based process, coordinated by the Variety Registration Office. Potential varieties must first be registered before being evaluated by recommending committees based on morphological, pathologic, agronomic, physiologic, biochemical characteristics, and kernel information. The significant difference to the process employed in Australia is that all nominated quality parameters must be at least matched by the new variety. In addition, each of the Canadian wheat classes "is visually distinct from the others, and the varieties within each class are visually similar. The Canadians refer to this visual characteristic as "kernel visual" distinguishability, or KVD, and it is a requirement that must be met if a wheat variety is to be registered for production" – Canadian Grain Commission, 2003. It is this aspect, combined with unwavering quality requirements, that some consider to have held back advancements in agronomic and quality performance of the Canadian wheat industry.

USA

In contrast, the system of classification is conducted on a less formal basis in the United States. Wheat is grown on a strictly regional basis. Potential varieties are considered by Wheat Quality Councils, funded by the various State Wheat Commissions, with quality testing being undertaken by four main regional laboratories of the US Department of Agriculture, central to the main class of wheat produced in the region. In addition, flour millers perform their own testing as a basis for the subsequent buying strategies. The provision of quality and agronomic information comes from trials conducted by the state-based universities and agricultural colleges, in addition to private companies.

Table 2 Base-rate returns in $/ton estimated as examples of value differences between specific grades

Grade of wheat	*Return Aust $/ton*
Australian Prime Hard (13% protein)	243.50
Australian Hard (11.5% protein)	232.00
Australian Premium White (10% protein)	224.00
Australian Standard White (10% protein)	212.00
Australian Premium Durum (13% protein)	262.00
Australian General Purpose (10% protein)	206.00
Feed Wheat	190.00

Estimates are FOB and GST-exclusive, assuming 5% screenings and 12.5% moisture, with the exception of Feed Grade, for which protein content and screenings are not specified.
Adapted from AWB Limited, Australia.

France

With almost half of French production now destined for export, it is important for France to have a variety regulation system. The system differentiates varieties into four end product classes. These are high-grade bread making (BPS), regular bread making (BPC), biscuit wheat (BB), and wheat for other purposes (essentially for stock feed or industrial uses) than bread making or biscuit making (BU). These grades are used in recommendation lists produced by the French Department of Agriculture on which farmers base their variety choice. To be listed, varieties must go through a 2 year official testing period, in which the new variety must be equal to the standard for both agronomic and quality measurements. The key quality measurements used to differentiate between the grades are the Alveograph and bread making tests.

General Philosophy

All this attention to the quality of the wheat traded shows that successful suppliers of wheat in the international market have mechanisms in place to ensure the consistency of inherent quality characteristics. The systems used are different, although, all have a common fundamental philosophy. All classify or group wheat varieties into a commercial type or style that is recognizable for its inherent processing features. The aim of grouping wheat varieties is to produce parcels of wheat that deliver a consistent product and hence, meet customer expectations. Unfortunately, classification of varieties on inherent characteristics is only half the equation, as the growing environment has a significant influence on quality.

Physical Quality – Harvest Classification

Although testing technology for inherent quality characteristics has yet to have broad adoption by the wheat industry, continued improvements have occurred in the assessment of physical quality. It was only 30 years ago that, in Australia, wheat was classified into the broad category of fair average quality (FAQ). This was around the same time that the Canadians introduced protein measurements to assist with the marketing of hard red wheats. Without accurate and quick methods for protein and moisture, wheat was segregated on the basis of cleanliness and visual soundness. Today, near-infrared (NIR) technology, along with a host of new technologies like single kernel characterization and image analysis, allow the assessment of protein, moisture, cleanliness, and, in the not too distant future, defects like stained grains and durum vitreousness.

All the major wheat-export countries have a range of classes or grades to reflect good and bad quality (Table 3). These not only separate the clean from the dirty, but also are recognized by buyers with respect to the end use of the wheat. Therefore the systems used have the dual effect of differentiating on the basis of physical traits, such as test weight and cleanliness, while also being readily identified by customers for certain attributes over and above the physical quality.

A key feature for ensuring that the wheat is segregated appropriately is testing at harvest. This has always been, and will continue to be, a challenge because farmers must deliver their wheat as quickly as possible (to avoid any possible harvest-weather damage), yet grain-handling agents appear to be delaying the delivery process by testing and segregating. At the very least, the time taken to perform testing is necessary, simply for the fact that once a delivery is poured down the grid, it is difficult to extract it back out if it has been binned incorrectly.

Australia

In Australia, the majority of wheat is delivered from the farm to a network of silos. It is against this first delivery that individual loads are measured for the range of physical and visual attributes. Most of these silos are managed by only a hand-full of private or farmer-controlled organizations, each with its own reference laboratories. Protein content, moisture, and cleanliness are measured objectively by NIR and specifically designed automatic shakers. Repeatable measurements are important for these attributes, as farmers are paid on the level delivered. Test weight and falling number are also objectively measured, but these serve to differentiate between grades and do not have incremental payment scales like protein content and moisture. Similarly, visual assessment of frost damage, stained grains, and vitreousness determine for which grade a delivery will be eligible. However, like in North America, research in Australia is pursuing the vexed question of objective visual assessment. Whilst NIR may provide some answers for objective assessment attributes like durum vitreousness, image analysis is likely to be able to assess a wider range of defects, which may in turn reduce the costs and testing time, making such technology more attractive for adoption by grain handlers.

The harvest assessment of Australian wheat determines how much the farmers are paid and where their wheat is stored. The quality results are aggregated electronically and then used in allocation of stock. When the analytical results are combined with variety composition, AWB Limited as the bulk

marketer of Australian wheat has a powerful tool in terms of knowing the physical quality (from harvest measurements) and intrinsic quality (from the variety composition). Grain is retested as it moves from country silos to port-loading facilities. Prior to shipment, wheat is again thoroughly tested to further refine the quality of stocks to meet customer's contract specifications. The final testing of the wheat occurs during loading, when representative samples are collected and then tested accordingly to customer requirements. In some instances, this may require milling and actual end-product assessment, and/or residue testing for chemical or pesticides according to government import requirements.

Canada

At the opposite end of the harvest quality-testing regime is the system used in Canada. Owing to the fact that the majority of storage is on-farm, the Canadian system, for ensuring that export wheat meets customer requirements, has a strong focus on measuring the quality of rail car lots from the elevator network as they begin their movement to port for export. It is commercial companies that assemble the wheat received from farmers to meet the requirements of the Canadian Wheat Board (CWB) through their quota system. Ensuring that the testing is performed to industry standards, the Canadian Grain Commission (CGC) licenses each silo operator and monitors their testing proficiency.

The unique aspect of the Canadian system is the reliance on KVD to segregate most farmer deliveries. Protein assessment occurs at the country silo for the top grades of the Canadian western red spring (CWRS) class, with other classes being tested at export terminals for protein. Generally, achieving the necessary protein level is not a problem in Canada, unlike in Australia where inherently poor and very old soils mean that to achieve higher levels, farmers need to actively manage their crop. When the KVD is done, the silo operator also determines the cleanliness of the delivery and whether or not cleaning is required to meet export standards. This is different from Australia, where the customer receives the aggregated cleanliness of the wheat as delivered by farmers, as wheat is not cleaned as it moves through the supply chain. Canadian farmers' payments are adjusted based on this "dockage" measurement.

Wheat is then moved to export terminals where CGC inspectors confirm the quality of the wheat being unloaded. Again, the higher grades of the CWRS class are protein analyzed. In addition to cleaning facilities, wheat can be dried if required. As occurs in Australia, a cargo sample is collected, upon which the CGC issues a "Certificate Final" which guarantees the quality and the weight of the wheat in the cargo. The regulated nature of the Canadian systems means that the CGC has strong governance of the product ultimately sold by the CWB whereas in Australia, AWB Limited relies on contracted third parties to load their wheat.

USA

Country elevators also play a key role in the movement of wheat in the United States. There are some 10 000 privately owned elevators throughout the wheat-growing areas of the United States. Either large grain-exporting companies, farmer cooperatives, flour milling companies and or other business enterprises own the country elevators. As occurs in other countries, a sample is taken of the delivery to determine its grade, moisture, and dockage. A division of the United States Department of Agriculture called Grain Inspection, Packers and Stockyard Administration (GIPSA) manages the government quality standards. The grade is determined on the basis of appearance, moisture level, and cleanliness as outlined in the US Grain Standards. If required, protein and falling number tests can be performed as required under customer contracts.

From the country elevator, wheat is transported by either rail, road, or river barges to larger central storage facilities that serve both domestic and export customers. At terminal facilities, wheat can be blended to achieve the specific quality requirements of different customers. Again, the United States has facilities that can clean wheat to lower specifications than those that apply to grain received at the country elevator. GIPSA representatives or licensed state and private agencies inspect all wheat exported as it moves through the supply chain from country silo to export terminal.

Unlike Australia or Canada, any individual or company meeting certain criteria can export US wheat. According to US Wheat Associates, "the export grain companies that merchandise US wheat are generally of three types:

- large, privately-owned, vertically integrated, multinational companies which have offices or representatives in most importing countries;
- smaller, privately-owned multinational companies which do not own or operate significant grain-handling facilities themselves, but maintain an international network of agents or representatives in importing countries; and
- cooperatively-owned firms or farmer-owned cooperatives that can compete as viable exporters.

Each type of exporter has access to the same sources of wheat supplies and all three types maintain well trained, technically competent staff who are able to coordinate the many facets of logistics, finance and governmental regulations necessary to transact international grain sales and deliveries."

As a large central quality-assurance agency, GIPSA is active in pursuing new technologies to be used in their inspection services. For example, prior to becoming part of GIPSA, the Federal Grain Inspection Service as it was known and Agricultural Research Service developed a method of differentiating wheats on the basis of hardness. This technology known as the "single-kernel characterization system" allows for an objective measurement of a grade sample to determine whether it is hard, soft, or mixed; rather than relying on visual and subjective assessment. On the pursuit of testing technology, Steve Tanner, Director, Technical Services Division with GIPSA, made the comment in 2002 that "the United States official system of grain-quality measurement technology is in transition. Currently, the system is comprised of a mixture of electronic, chemical, mechanical, and visual methods for assessing grain quality. Less costly and more objective methods are being developed. The cost of standardization and quality control must be minimized. Future goals must be: (1) rapid, accurate, low-cost, simple, easily standardized, and widely available testing methods and (2) new methods to measure functionality and value-added traits."

Europe

Unlike other exporters that differentiate between hard and soft wheats using grades or classes (akin to bread and biscuit wheats), the wheat classification system in Europe takes greater effort to differentiate between common and durum wheat. Given the environmental conditions and the prevalence of rain during harvest, the assessment of sprouted kernels and the use of falling number measurements have important roles in grading. Many European countries, in addition to measuring protein level, also focus on gluten level and quality.

The basis for differentiating wheat in Europe is strongly influenced by each country's baking methods. While France, Germany, and Italy have four classes, the regional preferences become evident with respect to baked products (e.g., the French baguette) and testing equipment (e.g., the Alveograph for France) when the quality specifications of each are examined (Table 4).

Looking at one of the major exporters, ~10% of French cereal production is retained on farms with the rest sold to collectors who clean, segregate, store, and

market the grain. With increasing production, more wheat is available for export and up to half of France's annual production may be exported. It has been estimated that there are 1100 of these collectors in France, with ~300 of them cooperatives managing 65% of cereal production. The remaining collectors are grain merchants and industrial users, such as for animal feeds and for starch manufacture, holding shares of 31% and 4%, respectively. The collectors have silos at over 7000 locations throughout France. These primary locations then can transfer grain to secondary sites in preparation for large export consignments or directly to domestic users, noting that some domestic mills have their own storage facilities.

To ensure that customers are familiar with the evolving French wheat crop, the Office National Interprofessionel des Cereales (ONIC) in association with the Institut Technique des Cereales et des Fourrages (ITCF) and the French National Millers Association, arrange for annual quality testing. Over time, these results have shown the strength of French wheat to be increasing and a higher proportion of sowings to involve the better quality varieties.

Argentina

Faced with increasing competition in the international market, the Argentine industry has recently taken a new approach to quality. With customers demanding security on quality, for the first time, protein content is now being regularly tested at harvest. This is, in addition, to an expanded testing regime to profile the overall quality of the wheat produced in the eight Argentine wheat regions. Farmers, elevator companies, and millers work together to collect representative samples based on nominated tonnages. These are aggregated to allow for testing of physical, milling, and dough properties by various laboratories around the country. This joint industry approach has now produced four Institutional Quality Reports, all of which have been published on the internet (www.trigoargentino.com.ar) starting with the 1999–2000 crop.

General Comment

The publications of crop reports that describe the physical and intrinsic quality of a country's wheat are now available for all the major exporters. The common goal is to demonstrate the general quality of the various wheat types available, but given the diminishing number of customers worldwide, such reports are becoming more of a historical reference point. Nearly all suppliers will meet with their customers postharvest to discuss the quality of the wheat available in the forthcoming shipment period, and at this time identifying any possible quality issues. Such meetings are not in isolation, with AWB Limited, the Canadian Wheat Board, and US Wheat Associates regularly meeting with customers both abroad and at home to discuss quality expectations and needs. That said, as a historical reference, the crop reports are ideal for tracking how the overall quality of a particular style of wheat may have changed over time.

Conclusion

It is anticipated that into the future, customers will become more demanding with respect to continuity of quality. Therefore, the quality systems of the major exporters will continue to evolve. This may occur due to new technologies that can, for example, quickly determine the dough strength of an individual delivery at harvest, perhaps removing the need to have a variety declaration. With ongoing reviews on trade barriers, changes may also occur with the industry structures of exporter countries, and this in turn could change the way in which quality is delivered. Needless to say, customers will pay for the quality delivered and if they do not like what they receive, this opens the opportunity for another supplier. The challenge is to understand customers' future requirements, and to have flexible systems of segregation and transport (both in terms of inherent and physical quality) to ensure consistency of grain quality.

Dry Milling

J E Dexter, Canadian Grain Commission, Winnipeg, MB, Canada
A K Sarkar, Canadian International Grains Institute, Winnipeg, MB, Canada

Introduction

Wheat may be used whole in various ways for human food but usually it is ground and/or fractionated in preparation for further processing. Roller milling is the most flexible and widely used procedure for grinding and fractionating wheat. Products of roller milling exhibit diverse composition and functionality, suitable for preparation of an almost limitless array of human foods.

The main fractions of wheat roller milling are flour (or semolina when milling durum wheat), bran, shorts, and germ. Bran consists of large flakes that are comprised of outer layers of the kernel and adhering aleurone. Shorts are finer bran particles, and usually contain some endosperm and germ.

Properties of roller-milling products are determined by roller-milling conditions and by intrinsic properties of the wheat being milled. Modern roller milling is a gradual process involving successive grindings and separations. Each flour stream has unique composition and functional properties. Judicious blending of specific flour streams allows millers to produce diverse custom flours of differing refinement and functionality.

The two main classes of wheat cultivated today are common wheat, often referred to as bread wheat, and durum wheat. To achieve best results, millers select wheat carefully on the basis of intrinsic quality and physical condition, and make process adjustments to mitigate variations in quality among wheat lots. Physical damage incurred by poor growing conditions and improper postharvest handling and storage, influences wheat-processing potential. Plant breeding has developed common wheat types of variable kernel hardness, protein content, and dough properties with quality traits suited for specific end products. Durum wheat, an ancestor of common wheat, is harder than the hardest common wheat and is usually milled into a granular flour, referred to as semolina, for manufacture of pasta and couscous.

Historical Background

Wheat milling is an ancient craft, dating back thousands of years to the dawn of civilization. Ancient wheat was hulled, unlike free-threshing modern

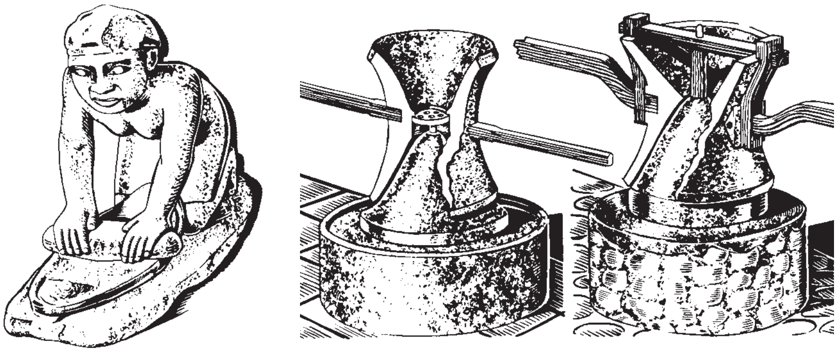

Figure 1 Saddlestone widely used in ancient Egypt (left) and hourglass stone mills used in Roman times (right). (Adapted from Sarkar AK (1993) Flour milling. In Bass EJ (ed.) *Grains and Oilseeds: Handling, Marketing, Processing*, 4th edn., vol. 2, pp. 603–653. Winnipeg, MB: Canadian International Grains.)

wheat. Primitive cultures ~10 000–12 000 years ago used a mortar and pestle to crush wheat to separate ground kernels from hulls. Implements evolved from primitive ones like stones and hollowed tree trunks, to more sophisticated objects designed and shaped to improve performance. In ancient Egypt, saddlestones were widely used (Figure 1). An upper stone was moved, back and forth by hand, over a lower stationary stone.

A great development was the invention of the millstone in Roman times. Rotary motion enabled the use of humans or animals to power the mill by traversing a circular path (Figure 1). Over time, advancements were made in stone shape and size. Other means of power were used to drive the millstones such as flowing water and wind, and eventually steam power. Initially, stone milling comprised a single intense grinding. A multistage grinding process with intermediate sifting came into being in Europe in the Middle Ages, which allowed recovery of relatively white flour.

The demand for white flour grew. The roller mill, purifier, and plansifter were developed in the eighteenth and nineteenth centuries, and led to the gradual break and reduction system. The addition of mechanical conveying allowed mechanization, and flour milling became a continuous manufacturing process. The basic process remains similar today but advances in design of equipment for cleaning and milling have allowed continuous improvement in reliability, production, sanitation, and overall efficiency. A major advance ~1945 was pneumatic conveyance of mill stocks. Today most flourmills feature computer control, and some are virtually fully automated.

Structure and Composition of the Wheat Kernel and Flour

Wheat-kernel structure is shown in Figure 2. The aleurone layer is part of the endosperm, but some remains attached to bran following milling. White flour originates from starchy endosperm, which comprises ~85% of the wheat kernel. In practice, even the most efficient roller mills fall short of that theoretical maximum yield of highly refined flour, because the crease, which runs along the length of the grain and reaches almost to the middle, makes perfect separation of endosperm impossible.

Wheat-kernel composition is heterogeneous. Starchy endosperm is much lower in mineral content than other constituents. Accordingly, flour ash content (mineral matter left behind after incineration) is a widely used index of flour refinement, low ash content being indicative of highly refined flour containing almost pure endosperm. Gluten proteins, which give flour dough viscoelastic properties essential for high-volume bread and firm pasta, are found in the endosperm. Germ is particularly rich in protein. The proteins in germ and bran are nongluten proteins that have better nutritional value than gluten proteins, but are not beneficial to processing properties. Bran contains most of the fiber in the kernel, also an important nutritional consideration.

As flour yield (or extraction rate, the proportion of wheat converted into flour) increases, contamination of flour by bran and germ increases. As a result, the nutritional value of flour improves as flour yield increases. However, flour-processing quality and shelf life diminish at higher yield. The presence of bran disrupts the gluten protein matrix, weakening dough properties and reducing gas-holding capacity of dough during fermentation. The presence of bran also results in darker end products, detracting from aesthetic appearance. Germ reduces dough strength because it contains low-molecular-weight sulfydryl compounds that break disulfide cross-links, reducing the size of gluten-protein polymers that impart elasticity to dough. Germ also reduces flour shelf life due to oils and enzymes that promote rancidity.

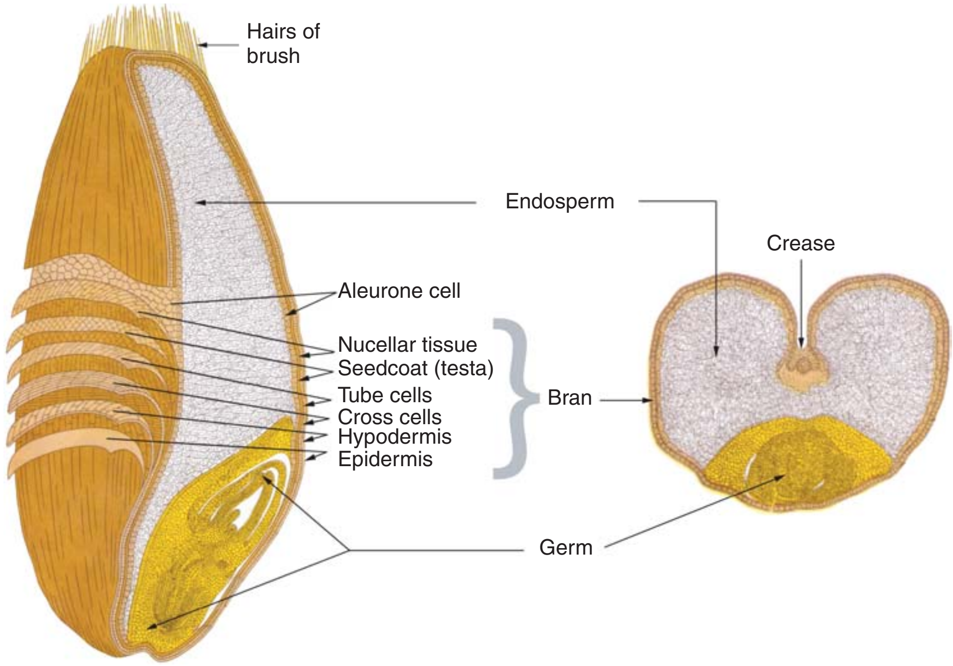

Figure 2 The structure of the wheat kernel sectioned longitudinally (left) and transversely (right). There are six bran layers. The crease, which runs the full length of the kernel prevents fully efficient separation of bran from endosperm. (Courtesy of North American Millers Association, with permission.)

Wheat Reception and Storage

Wheat may arrive at mills by truck, rail, or ship (Figure 3). Wheat is weighed, and a representative sample is taken for analysis prior to storage. Wheat analyses may include content of foreign material and damaged grains, test weight (weight per unit volume), protein content, and moisture content. The lot is then transferred to a bin, where wheat of comparable physical condition and similar end-use potential is stored, assuring that quality characteristics are preserved, and used to the best advantage.

On the way to storage, wheat generally undergoes precleaning. First, a magnet removes ferrous metals. Then a high-capacity grain cleaner, with shaking or rotating screens, removes rubble, and fine dust. This cursory cleaning protects equipment downstream, makes more efficient use of storage space, and improves wheat-storage stability.

Wheat Blending

Wheat may be milled individually, or as a blend. The objective of wheat blending is to meet quality requirements at minimum cost. Blending can create quality attributes lacking in individual wheats. Having the right quality is critical to maintain customer satisfaction and market share. Blending of inexpensive low-quality wheat with the high-quality variety can achieve the desired quality at reduced cost.

Ideally, blending is performed following cleaning and conditioning. Different wheat lots may have different kernel size, making cleaning individually more efficient. Wheats of varying hardness have differing optimum milling moisture and conditioning time. Convenience, cost, and storage limitations often necessitate blending prior to cleaning and conditioning.

Wheat Cleaning

Efficient wheat cleaning prior to milling is critical. Foreign material such as stones, metal, unthreshed grain, badly damaged kernels, and foreign seeds either adversely affect flour quality, or are hazardous to milling equipment. Most impurities are quite easily separated from wheat on the basis of size, shape, density, or magnetism (Table 1).

Figure 3 shows how cleaning machines would be arranged in a typical wheat-cleaning scheme. A magnet removes ferrous materials that may cause serious damage to subsequent equipment. Magnets are also used throughout cleaning to remove any "tramp" metal which surfaces from equipment or is introduced inadvertently.

It is important to remove impurities as early as possible to reduce load on subsequent equipment and increase cleaning efficiency. A grain separator uses sieves and aspiration to remove impurities. The top screen removes large impurities, such as

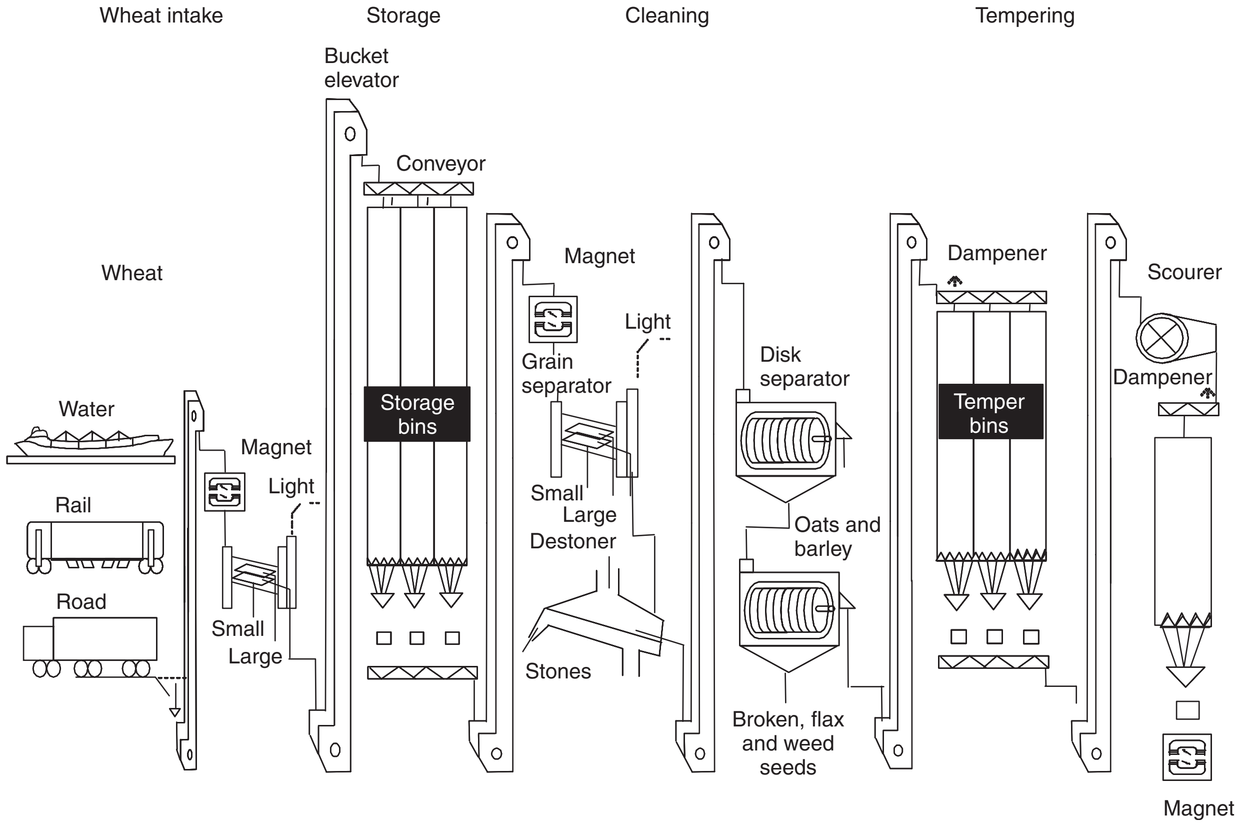

Figure 3 A simplified wheat intake, cleaning, and conditioning diagram.

Table 1 Examples removing impurities from wheat on the basis of physical properties

Physical properties	*Foreign material*	*Cleaning equipment*
Size	Larger than wheat: large stones, wood, corn, peas Smaller than wheat: rapeseed, flax, sand, dust	Grain separator or millerator
Density	Similar size and shape but heavier: small stones, mud balls, glass Similar size and shape but lighter: ergot, damaged light wheat	Destoner, combinator, gravity table, gravity selector
Shape	Similar cross-section but shorter: broken wheat, wild buckwheat Similar cross-section but longer: oats, barley, wild oats, ergot	Disk separator or indented cylinder
Air resistance	Lighter than wheat: chaff, husk, light dust, thin kernels, insects, damaged light kernels	Aspiration
Magnetism	Ferrous objects and alloys containing iron: nuts, bolts, washers, nails, shavings	Magnets

Adapted from Sarkar AK (1993) Flour milling. In: Bass EJ (ed.) *Grains and Oilseeds: Handling, Marketing, Processing*, 4th edn., vol. 2, pp. 603–653. Winnipeg, MB: Canadian International Grains Institute.

maize, soybeans, and unthreshed wheat. Small weed seeds and broken kernels pass through the bottom sieve. Wheat falling off the bottom sieve is aspirated to remove chaff, dust, and shriveled kernels.

A destoner removes materials that can cause unnecessary wear and tear, such as stones of similar size to wheat. An upward air current is passed through a sloped oscillating metal screen. Wheat floats on an air cushion and moves down the slope by gravity. Denser materials, such as mud balls and small stones, make more contact with the screen. They are propelled up the slope and are collected separately.

Disk separators remove remaining impurities that differ in length to wheat kernels, but are of similar density and cross-section. Disks revolve in a vertical plane through the wheat. The surfaces of the disks

have numerous pockets that pick up objects that are short enough to lodge in the pockets. There are generally two units. The first picks up wheat while rejecting kernels longer than wheat, such as oats and barley. The second picks up small seeds and rejects wheat.

A recent innovation is to separate wheat into a heavy stream (~70–80% of total) and a light stream following the grain separator. The heavy stream, after removal of stones, goes directly to conditioning, whereas the lighter stream passes through the remaining cleaning equipment. Savings in capital investment and operational cost savings are realized because the bulk of the cleaning equipment is required for only ~20–30% of the wheat.

Wheat Conditioning (Tempering)

After cleaning, wheat is conditioned by addition of tempering moisture, and moist wheat is rested in bins (Figure 3). Conditioning optimizes separation of bran from endosperm during milling. Bran is toughened, reducing bran powdering, and lessening bran contamination in flour. Endosperm hardness is also reduced, facilitating reduction into flour.

Achieving optimum moisture level for milling is critical. Too much tempering moisture reduces flour yield because complete separation of bran from endosperm is more difficult to achieve, and sieving efficiency is reduced. Too little tempering moisture results in bran powdering, which contaminates flour.

Spray nozzles add tempering water in an enclosed screw conveyor. Modern tempering equipment features electronic control and vigorous mixing action to ensure that precise and uniform addition of moisture is achieved. Online moisture measurement, operating in feedback mode, allows moisture addition to be continuously regulated to the desired level.

Optimum tempering moisture varies among wheat types. Soft wheat is tempered to lower moisture than hard wheat. A tendency for soft-wheat stocks to be sticky and more difficult to sift than hard-wheat stocks is exacerbated by higher moisture content. Following tempering, wheat is stored in bins to allow penetration and uniform distribution of moisture. Optimum rest time varies from several hours to more than a day depending on wheat moisture content and hardness. Soft wheat does not need to rest as long before milling as hard wheat. Soft wheat endosperm is more porous than hard wheat endosperm, so water penetrates into soft wheat endosperm more quickly.

Wheat is often tempered in two stages with resting time between stages, particularly when a large amount of tempering moisture is added. Addition of tempering water is limited to ~3% in conventional tempering equipment. Modern intense mixing equipment allows higher moisture levels to be added, and sometimes eliminates a two-stage tempering requirement.

After conditioning, wheat is scoured. Scourers use steel beaters to throw wheat against a wire screen. Dirt and loosened bran, which would contaminate flour, pass through the screen. Commonly, wheat is sprayed lightly immediately before milling. Up to 0.5% water is added, and the sprayed wheat is held in bins for ~30 min. The purpose is to toughen bran, and reduce bran powdering. The wheat is then weighed, and passed through a magnet to remove ferrous metal fragments prior to milling.

Mill Equipment

The most important equipment in modern flourmills are roller mill, plansifter, purifier, and bran duster. Equipment from different suppliers varies in design, engineering, reliability, and price, but all have similar working principles.

Stock is ground by a pair of closely spaced grinding rolls (Figure 4). In each roller mill, two pairs of rolls are housed back-to-back within a cast iron frame. One pair of rolls is accessed on each side of the roller mill. Each roller pair is driven separately and has separate feeding and adjustment mechanisms, allowing different stocks to be fed to each roll pair. Recently, roller mills with four pairs of rollers have become available. Two pairs are stacked vertically, with the upper pairs feeding the lower pairs directly. They are gaining in popularity because they allow an economical way to increase milling capacity.

Stock to be ground is distributed evenly over the entire length of grinding rolls by a feed control device. The feed control device consists of a balanced feed gate and a pair of feed rolls. The balanced feed gate regulates flow of stock. Feed rolls facilitate smooth flow of stock precisely into the "nip" of the grinding rolls.

Grinding rolls are cast iron cylinders with a hard "chilled" surface to resist wear. Rolls are either 225 or 250 mm in diameter, and lengths are usually 800–1000 mm. Each pair rotates inwardly in opposite direction and at different speed. A transmission belt drives the fast roll, and the slow roll is driven from the fast roll by either a gear or chain drive. The ratio of roller speeds, known as differential, imparts shear to grinding action. The slower roll holds the stock, while the faster roll compresses and shears it. For most effective performance, break rollers have a differential of ~2.5 : 1, compared to 1.25 : 1 to 1.5 : 1 for reduction rollers.

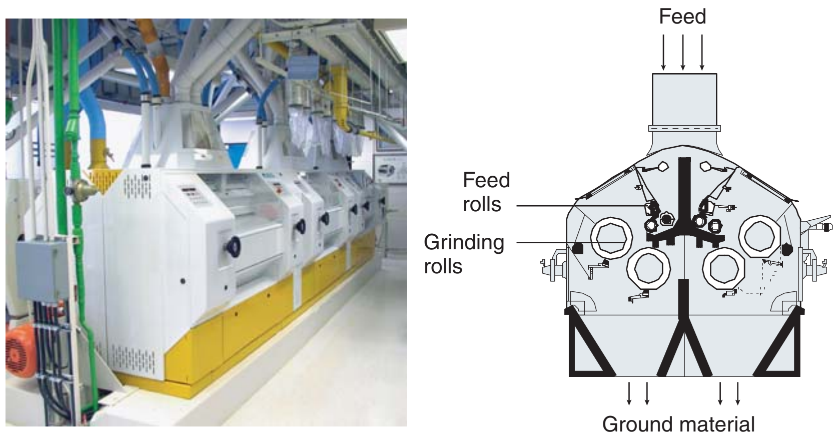

Figure 4 Modern roller mills. External view of roller mills (left) and schematic view of a roller mill (right).

Reduction rolls are commonly smooth with a frosted (slightly rough) surface to impart some shear to the grinding action. Break rolls are corrugated, corrugations becoming finer (more rows per cm) with each break as stock becomes finer. Corrugations are cut in a spiral pattern along the length of the roller. Spiral prevents rolls from locking and imparts a scissor-like cutting action.

Sifting is performed by plansifters, commonly known as sifters (Figure 5). Plansifters are suspended from girders by canes and are driven by a rotating vertical shaft with attached balanced weights. Rotation is on a horizontal plane in a circular motion, such that a pencil fastened to the bottom of the sifter traces a circle. The diameter of the circle is termed the "throw." Sifters have a throw from 75 to 100 mm and rotate from 180 to 225 rpm.

Plansifters may have four, six, or eight sections. Each section has a stack of 14–30 layers of sieves. Each section is independent and has its own feed inlet at the top of the sifter. Sieves consist of a wooden frame with a coarse wire grid bottom to hold "cleaners," which are plastic or cotton pads. Cleaners keep the underside of the sieve clothing clean, and help keep openings clear. Sieves are stretched and secured to frames by staples or glue. Apertures of sieve clothing range from ~1600 μm to less than 100 μm. Coarser clothing is composed of wire mesh while finer clothing is composed of nylon or silk. Sieve frames are inserted into outer frames with collecting trays. Coarse material tails over the top of sieves, and fine material passes through the sieves and is collected in the trays.

Purifiers take advantage of the greater density of pure endosperm particles compared to bran-rich or germ-rich particles of comparable size (Figure 6). A purifier has two sections, each section consisting of two or three layers of oscillating sieves. Sieve frames are mounted with a slight downward slope, and an eccentric drive generates longitudinal oscillation. A controlled air current passes upwards through the sieves.

Figure 5 A plansifter with doors on the nearest two sections open for viewing. In the second section, the sieve stack has been pulled forward and in the first section some of the sieves have been pulled. The canes supporting the plansifter are visible in the foreground.

Graded stock from a sifter enters one section of the purifier through a feed inlet. Stock is distributed

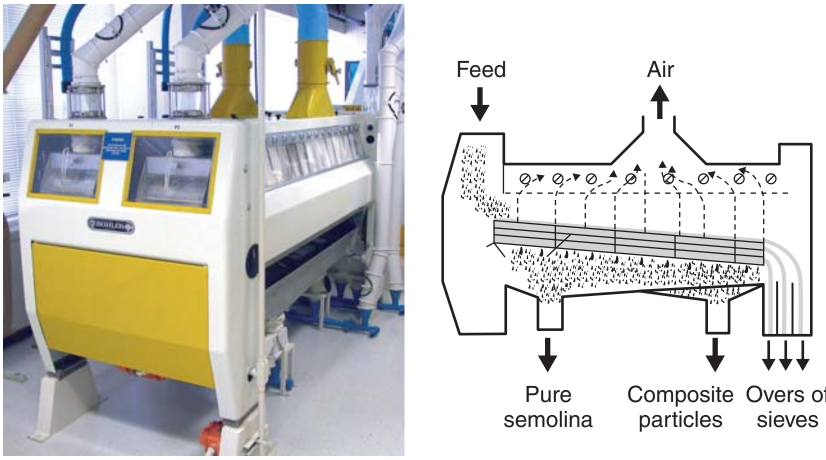

Figure 6 A triple deck purifier. External view (left) and schematic diagram (right).

uniformly across the width of the sieve. The frame is clothed with four sieves of progressively coarser aperture from head to tail. Sieve openings are kept clear by brushes, which move back and forth on guide rails under the sieves.

The sloped oscillating sieve promotes downward movement of stock in a layer. Controlled air currents drawn up through the stock stratify stock layers so that light bran-rich particles rise to the surface. Heavier endosperm particles fall to the bottom of the layer and pass though the sieve if the aperture is large enough. Composite particles with bran or germ attached remain in the middle of the layer. Thus, air flotation and sieving action combined allow separation into fractions that are progressively coarser and more contaminated by bran and germ from head to tail.

Bran finishers use impact to remove endosperm attached to broad bran at the end of the break system (Figure 7). The same machine, when used to remove endosperm from shorts (fine bran from the end of the break system), is commonly referred to as a shorts duster. Bran or shorts is fed into a horizontal cylinder. The lower part of the cylinder is perforated. Endosperm is scraped from bran or shorts by rotating finger beaters attached to a central shaft. Endosperm passes through the perforations and bran or shorts passes through the cylinder and is collected separately.

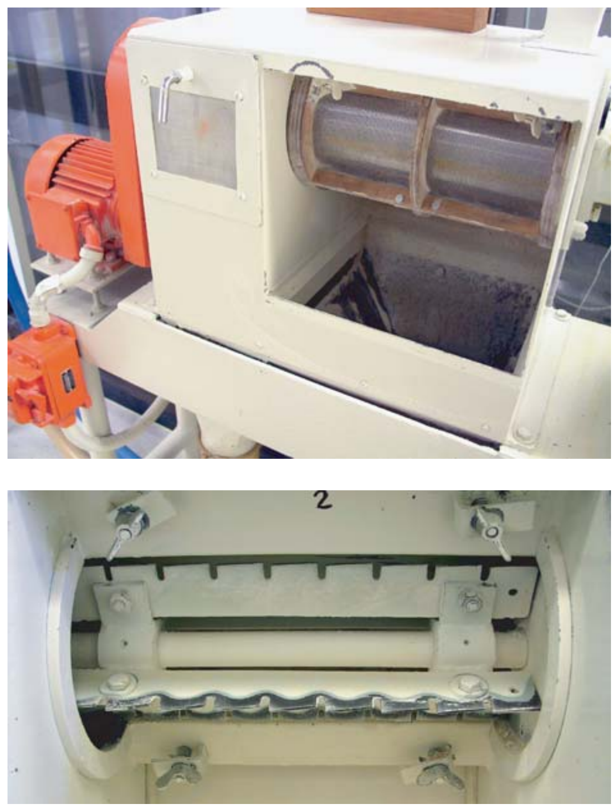

Figure 7 Bran finisher. View with front cover plate removed to show the metal screen (top), and view with screen removed to show finger beaters (bottom).

Hard Common Wheat Milling

Figure 8 is a simplified typical hard common wheat flourmill flow, designed to give a flour yield of ~75%. The main stages of milling are the break system, intermediate processing, which includes purification and sizing, and the reduction system.

The purpose of the break system is to separate bran from endosperm as efficiently as possible, although a small amount of flour is produced. The entire break system usually consists of four or five passages. The first break opens the wheat kernels, and ground material proceeds to the first break sifter, where particles are separated by size. The largest particles, consisting of wheat bran and adhering endosperm, are conveyed

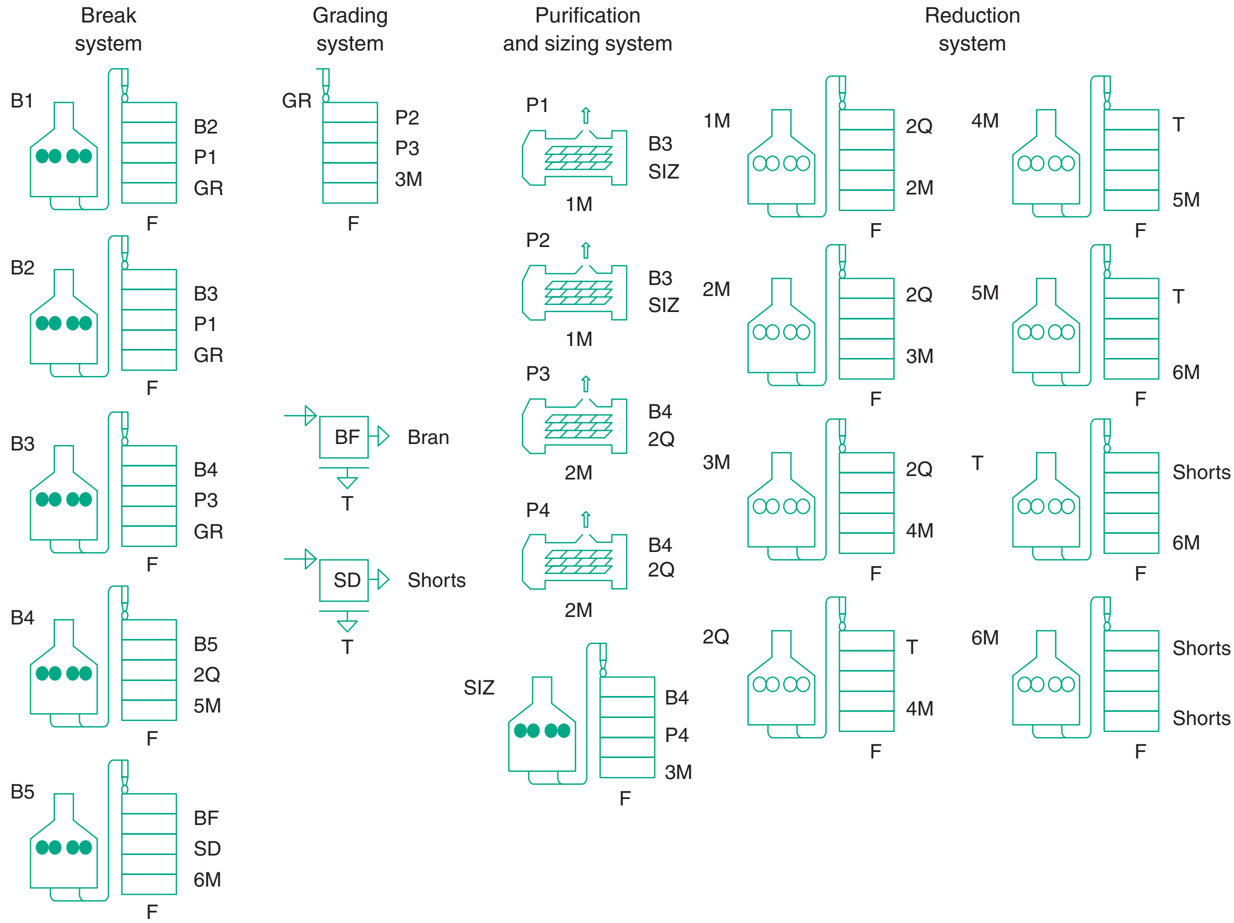

Figure 8 A simplified hard common wheat flour mill flow diagram. B, break; BF, bran finisher; GR, grader; M, middling; P, purifier; Q, quality; SD, shorts duster; SIZ, sizing; T, tailing. Corrugated rollers are closed and smooth rollers are open. (Adapted from Sarkar AK (1993) Flour milling. In Bass EJ (ed.) *Grains and Oilseeds: Handling, Marketing, Processing*, 4th edn., vol. 2, pp. 603–653. Winnipeg, MB: Canadian International Grains.)

to the second break rollers. Ground stock is once again sifted and the coarsest fraction sent to the third break passage. Each successive break and sifting passage separates more bran from endosperm. The coarsest fraction of bran from the last break proceeds to a bran finisher, and shorts proceed to a shorts duster, to remove the last traces of adhering endosperm.

Finer stocks from break sifters consisting of semolina (coarser particles), middlings (finer particles), and some flour are separated by a sifter referred to as a grader. Semolina and middlings are conveyed to purifiers that separate pure endosperm particles from bran-rich material. Essentially, pure endosperm particles are sent to the beginning of the reduction system where they are reduced into flour.

The coarser less-pure materials from purifiers proceed to the sizing (scratch) system. The primary objective of sizing is not to make flour, but to remove bran adhering to middlings. This is accomplished by light grinding on finely corrugated rollers. Ground stock is then sifted and purified before continuing on to the reduction system.

The reduction system is the heart of the flourmilling process. Carefully sized and purified middlings are reduced into flour gradually by successive grinding and sifting. Germ is flattened rather than reduced by smooth reduction rolls, and can be recovered as a coarse fraction by sifting.

Reduction grinding conditions are carefully controlled to produce as much highly valued prime-quality flour as possible. If grinding is too severe, bran contamination is increased, reducing flour brightness. Severe grinding can also excessively damage starch granules, adversely affecting flour functionality.

Divide Milling

A flourmill may produce single or multiple grades of finished flour from a given wheat or wheat mix.

Table 2 An example of typical yields and composition of flour streams (in ascending order of ash content) from milling of hard common wheat of about 13.5% protein content

Stream	*Yield (%)*	*Ash (%)*	*Protein (%)*	*Bread volume (cc)*
Middling 1	21.2	0.33	11.5	1000
Middling 2	13.0	0.40	13.0	1060
Sizing 1	3.4	0.40	12.6	1050
Sizing 2	4.6	0.40	11.6	910
Middling 3	8.4	0.44	11.9	850
Break 1	4.4	0.47	13.8	1020
Break 2	3.4	0.48	15.4	1020
Break 3	3.2	0.57	18.1	1060
Middling 4	4.2	0.82	13.6	810
Middling 5	2.3	1.00	13.5	650
Break 4	1.5	1.23	20.9	890
Middling 6	2.8	1.49	14.2	440
Bran finisher	1.7	2.61	21.1	620
Straight grade	74.1	0.55	13.2	1060

Adapted from Izydorczyk MS, Symons SJ, and Dexter JE (2002) Fractionation of wheat and barley. In: *Whole-Grain Foods in Health and Disease*, pp. 47–82. St. Paul, MN: American Association of Cereal Chemists.

Individual flour streams exhibit variable composition and processing quality (Table 2). Flour millers may combine all flour streams to produce "straight-run" or "straight-grade" flour. A more complex alternative is to produce several flours with different properties by judicious blending of streams. This is known as "divide" or "split-run" milling, and allows millers with demanding clients to increase return by closely targeting specific processing requirements. The whitest, most bran-free, reduction flours may be combined to produce highly refined "patent" flour, often marketed as household flour. Remaining patent flour, when blended with early break flours, gives a strong bakery flour of high protein content. Late break flour, late reduction flour, and bran finisher flour are heavily contaminated by bran and makeup lower quality "clear" flour.

Figure 9 shows how flour streams leaving sifters can be directed to any one of three flour conveyors to make divide flours. Divide boards can be used to further blend divide flours to make custom flour blends. In the upper example, a portion of the first patent flour is diverted on a divide board and blended with the second patent to make a strong industrial bakers' flour. In the lower example, the divide board is positioned to blend all three divide flours together to create a straight-grade flour.

Flour Additives

Additives are commonly used to improve flour-nutritional value or to improve processing quality (Table 3). Endosperm, the main component of flour, is poor in vitamins. Many countries have legislation requiring addition of vitamins and minerals to improve flour-nutritional value.

Flour can be made whiter by bleaching agents, like benzoyl peroxide. Other additives, known as improvers, include various enzymes of either fungal or grain origin and agents to improve dough strength and baking performance. Additives are available in powder form and are dispensed directly into flour conveyors using powder feeders.

Soft Wheat Milling

Soft wheat breaks down more quickly than hard common wheat. More flour is produced on the break system for soft wheat than for hard wheat, requiring greater sifting capacity for the former. Endosperm of soft wheat adheres more strongly to bran, reducing flour extraction rate expectations by up to 2% unless sifting capacity is increased. Yield of semolina and middlings is lower, so purifiers are of less importance, and often are absent. Stock is stickier and fluffier, which makes it more difficult to sift than hard wheat stock. Soft wheat is fed more slowly to the mill to facilitate sifting, and to ensure that stock flows freely through the mill.

Durum Wheat Milling

Durum wheat mill flows are different from common wheat mill flows, because the product preferred for premium pasta and couscous is uniformly sized semolina. Durum wheat flour that is unavoidably created as a by-product of semolina milling is of lower value. A typical durum wheat semolina mill flow is shown in Figure 10.

Durum wheat is very hard, which facilitates high yield of semolina. The break system for durum wheat is extended to allow gradual breakdown of kernels to achieve maximum production of semolina and minimum production of flour. Purified semolina from the break system is uniformly sized and freed from adhering bran by repeated sizing, grading, and purification. Most semolina is from sizing purifiers, making durum mills readily recognized by the large number of purifiers.

Milling By-Products

By-products of milling are an important economical consideration in flour milling. These include impurities from the cleaning house (screenings), mill feed (bran and shorts), and germ. Screenings, with the exception of metal, stones, and mud balls, are usually ground and sold for animal feed. Bran and shorts are

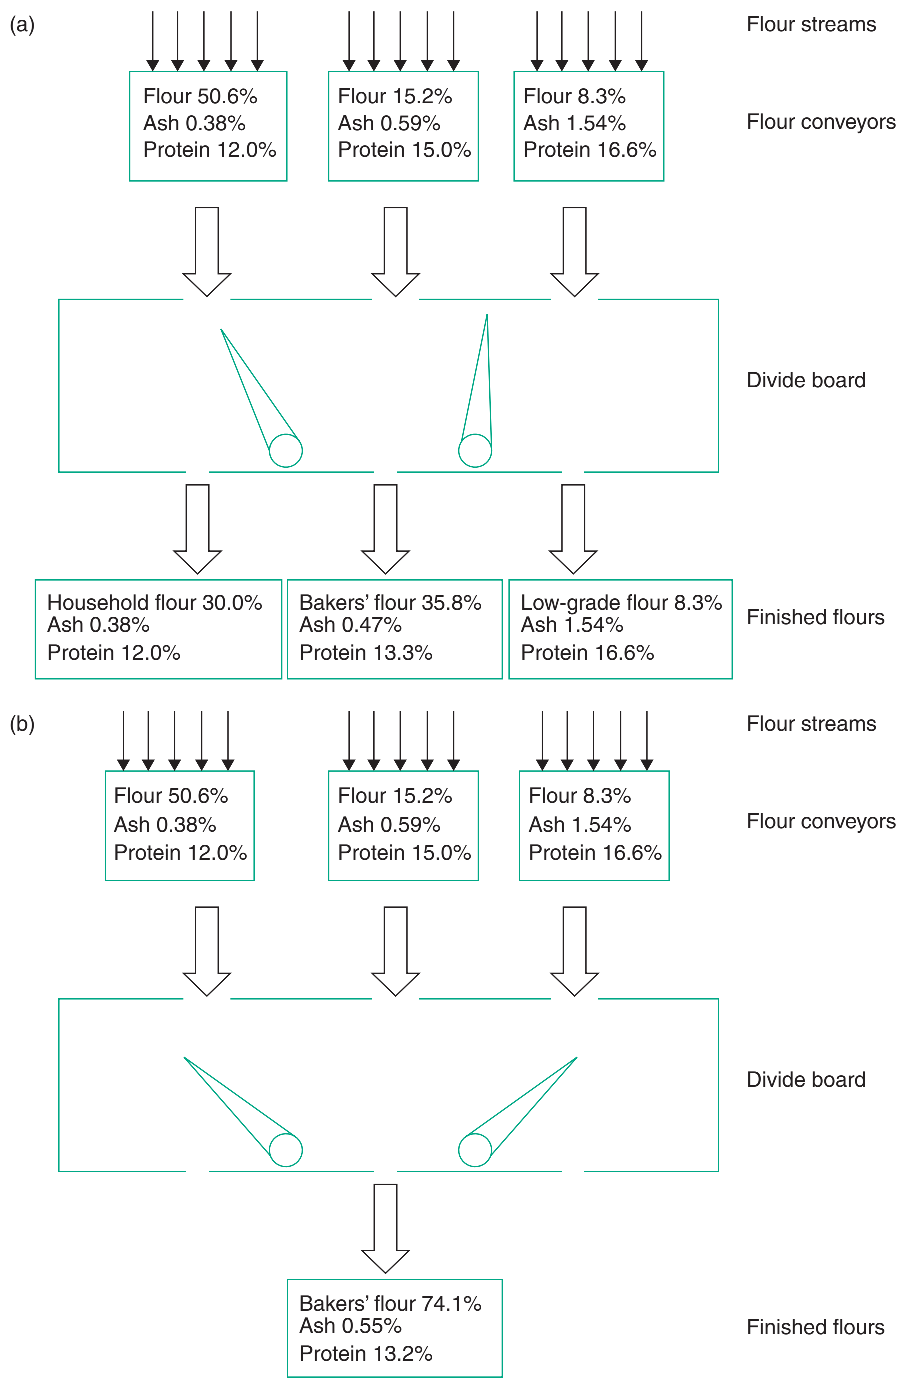

Figure 9 Examples of divide milling, where three custom flours are being produced from a single wheat mix based on streams shown in Table 2. Streams are collected to yield high-quality patent, second patent, and low-grade flours. In (a), part of the first patent is diverted by a divide board to blend with the second patent to make a bakers' flour. The remaining first patent would find use predominately as household flour. In (b), the divide board is positioned to blend the three divide flours to create a straight-grade bakers' flour.

also primarily used as animal feed. Depending on market conditions, bran also finds use for foods such as breakfast cereals and high-fiber specialty wheat products. Wheat germ is highly valued because of its excellent nutritional composition, and many mills have sophisticated germ recovery systems.

De-Branning (Preprocessing)

Wheat de-branning, or preprocessing, removes bran layers sequentially by friction and abrasion stages in modified rice polishers prior to milling. De-branning is gaining acceptance for durum wheat semolina

Table 3 Some commonly used flour additives

Additive	*Physical state*	*Approximate usual rate of application (ppm)*	*Purpose*
Vitamin-mineral premix	Powder		Nutritive supplement
Folic acid		1.5–2	
Iron		30–45	
Niacin		35–65	
Iron		30–45	
Thiamin		4.5–8	
Riboflavin		3.5–5	
Potassium bromate[a]	Powder	10–20	Oxidation
Azodicarbonimide[a]	Powder	2–20	Maturing, oxidation
Ascorbic acid	Powder	70	Baking improver
Benzoyl peroxide[a]	Powder	50	Bleaching
Chlorine[a]	Gas	1000–1400	Bleaching, maturing
L-cysteine hydrochloride	Powder	30	Shorten dough mixing time
Fungal α-amylase	Powder	As required	Increase yeast gas production

[a] Banned or restricted use in many countries.

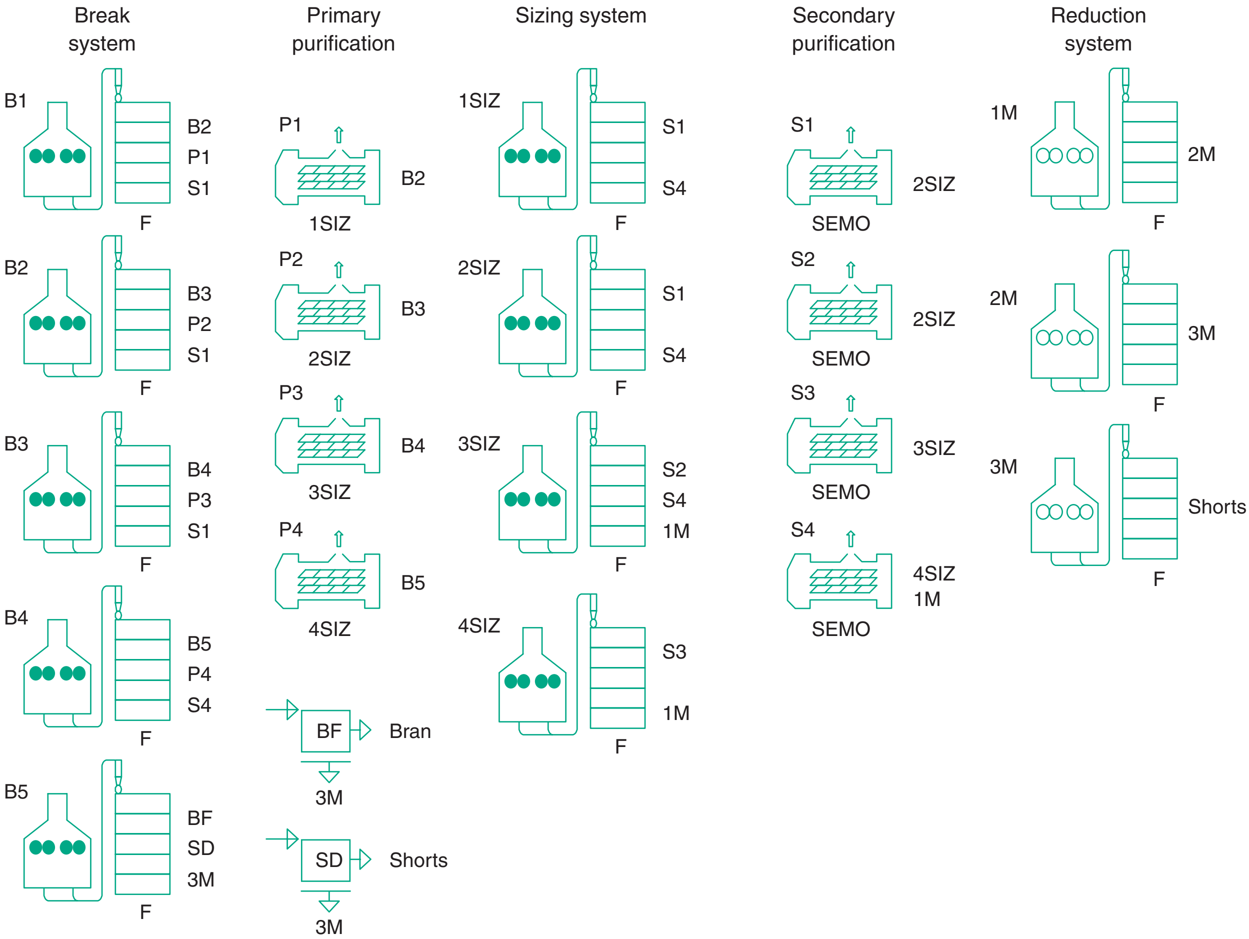

Figure 10 A simplified durum wheat semolina mill flow diagram. B, break; BF, bran finisher; M, middling; P, purifier; SD, shorts duster; S or SIZ, sizing. Corrugated rollers are closed and smooth rollers are open.

milling. Yield and refinement of semolina are significantly improved by de-branning. Top quality durum wheat can be milled more efficiently, or, alternatively, lower quality durum wheat can be used to produce semolina within customer specification. Evidence that de-branning improves milling performance of common wheat is less conclusive.

De-branning lowers capital investment because mill flow is shortened (the break system is almost eliminated), permitting more compact plants for a given capacity. During de-branning, individual bran layers are stripped off in sequence, whereas all bran layers are removed together by conventional roller milling. Each bran layer has distinct physico-chemical and nutritional properties, giving de-branning by-products great promise as novel food ingredients.

Milling Process Monitoring and Control

All electrical motors driving equipment are sequence controlled and interlocked to provide ease of operation, control, and protection. This allows sequential starting and stopping of motors and stopping of the process in a fail-safe manner. Process control functions may allow the entire process to be automated, depending on the extent of various types of sensors, switches, and high-level and low-level indicators. Conventional control systems have mimic display diagrams of the process, and a hard wired electro-mechanical relay control system for control functions.

Since the early 1980s, there has been a transition to mill automation. Mimic panels with small pilot lights are being replaced by computer graphics for visual display of the process status. Programmable logic controllers (PLC) are replacing hard-wired control relays. Computerized process control offers the flexibility of changing control functions, if required, through simply making programming changes rather than changing hard wiring. It also allows full integration of critical functions relating to process control and performance evaluation, such as product yield calculations and automated roll gap adjustment. Computerized process control has reduced labor requirements in flourmills. Some mills have so-called "lights out" operation, where the mill runs for extended periods without staff present in the mill building.

Another important advance is on-line quality monitoring. Automated on-line quality monitoring systems continuously monitor factors such as moisture content, protein content and flour color, allowing flour millers to efficiently meet customer specification.

Marketing

G C Worden, Canadian Wheat Board, Winnipeg, MB, Canada

Introduction

Wheat marketing is conducted in many formats around the world. At one extreme is a highly regulated central government control of wheat movement from field to the flour mill and even beyond, with controls over flour to bakeries and other processors. At the other extreme is a total "free market" system of supply-and-demand forces determining production, price, quality levels, movement, and availability. This article presents information on the major players in global wheat trade and differences in their wheat marketing systems. Evolutionary changes in the last few years that have had significant impact on wheat marketing are commented upon. Durum wheat is considered as part of the discussion on wheat marketing, with mention of unique characteristics of durum marketing where necessary.

Global Wheat Production and Trade

Annual global wheat production during 1990s has averaged ~570 million tonnes (Mt) but global wheat trade (defined as commercial export or import from one country to another) is less than 20% of that level, averaging just over 100 Mt. There are only five major wheat producing regions that contribute to over 80% of that trade. According to the Canadian Wheat Board 2002–03 statistical tables, based on a ten-year average (1993–2002), the leading wheat exporters have been (with their percentage market shares): United States (27.7%), Canada (16.3%), European Union (EU 15.0%), Australia (13.7%), and Argentina (8.2%).

The major wheat producers (with ten-year (1993–2002) average annual production) are China (93.9 Mt), EU (91.7 Mt), India (68.8 Mt), US (53.3 Mt), Russian Federation (46.9 Mt), Canada (20.6), and Australia (19.4 Mt). China, India, and the Russian Federation, although major producers, tend to be virtually self-sufficient. However, these countries can have swings in production, either due to weather impact or political decision, that can turn them into major importers or exporters. When this occurs, there is a tendency for this kind of unusual supply or demand to impact on prices and movement from the more traditional exporters.

There are some regions or countries that are strong traditional buyers of wheat. In the past, this included the former USSR and China, but they have recently improved their infrastructure to require less imported wheat. With the breakup of the Soviet Union, the individual countries from that region have started to adopt more of a free market mentality that has had an influence on global trade, to be discussed later, but for the most part tend to deal with inter-trade between themselves. China went through a period in the late 1990s where government policy encouraged build up of reserves of wheat. Over the last few years however the policy has changed to promote different agricultural priorities and the reserves are being depleted, to the point where China may again become a major buyer of wheat over the next few years. Currently (2003), the major buyers of wheat who have made annual purchases of greater than 3 Mt (based on ten-year average annual purchases during 1993–2002), are Brazil, Egypt, Japan, Algeria, Iran, Russian Federation, China, South Korea, Indonesia, and EU.

Feeding the people of a nation is a priority for many governments, obviously necessary to avoid unrest and to encourage progress. Therefore, agricultural policy in numerous countries introduces factors that can impact or distort free trade activities. There are many

examples of state-owned buying agencies that are totally responsible for purchase of agricultural goods from farmers within the country as well as for imported commodities. These are slowly reducing in number but are still a significant part of world trade. In some cases, liberalization takes place as the state-owned buying works in parallel with private trade during a phasing-out period. Examples of importing countries where central purchasing and controls are still in effect include China, Egypt, Japan, Algeria, and Iran.

On the exporter side there are two levels of intervention.

1. For Canada, Australia, and Argentina there has been direct action through government-legislated marketing agencies that have differing levels of influence in the sales of wheat from those countries. Recently, Argentina has moved to a private system. In Australia, although the marketing has been privatized, government legislation still provides the marketing agencies with single-desk authority over all export wheat sales. Canada also maintains single-desk authority through legislation for the majority of the wheat-growing area of the country.
2. The US and EU assume a more indirect influence by providing wheat price supports, deficiency payments and set-aside payments directly to farmers to subsidize income levels when returns are lower. In addition, governments in these regions provide further market-distorting tools such as export subsidies, government buying programs and other support mechanisms. In general, marketing activity is conducted by private trade and the governments provide direct payments to farmers through the income support structures.

A great deal of global wheat trade is conducted by major multinational companies that buy and sell a number of agricultural and other commodities. The scale of activity from these companies ranges from a local office buying wheat from a few farmers and brokering it to a nearby flour mill all the way up to a several thousand tonne sale from a major exporter to a major importer. Besides making the sale, these companies also arrange shipment, often by chartering the ocean vessel, and can arrange all the financial transactions including credit arrangements, letters of credit and securing all the inspection and certification requirements.

Some of these organizations are vertically integrated, involved in the processing of the same commodities they trade. Examples are Cargill Inc., Bunge and Louis Dreyfus. Many of these companies have existed for several years, having grown and diversified to take on additional activities. There have been considerable changes in terms of movements, takeovers, and acquisitions of various companies in the area of grain trading.

Marketing Overview

International trade in wheat is conducted by three basic marketing methods:

1. Government agencies or delegated representatives call for *public tenders* for a specific time period, referred to as a position. The call for tender outlines the terms for the purchase, including quantity, class, grade, and quality specifications, delivery period, payment terms, discharge port, and other details necessary for the bidder to make an educated and appropriate price offer. Major importers that use public tenders include Japan, Egypt, Tunisia, Taiwan, Philippines, and Algeria.
2. Private milling or end-use companies call for a private tender. Some government agencies may also use a private tender. The buyer privately calls for a bid from an exporting company or agency to meet desired specifications. There is often a pre-existing relationship between buyer and seller with knowledge of the quality available from the supplier and of the terms and delivery conditions from the buyer. Flour mills in the EU, Latin America, and many parts of Asia usually conduct private tendering.
3. Trade can take place in an open marketplace, referred to as a spot market, where wheat of specific quality and quantity is traded on a position basis. The Rotterdam market along with a few other EU ports are the only true open spot markets actively trading at present. Wheat from many different origins owned by private traders is offered for immediate or future delivery with prices reflecting market conditions. Many smaller flour mills in the EU purchase their milling wheat requirements in this type of open market.

For any of the marketing methods it is critical that there is a clear understanding of quality and other contractual expectations between buyer and seller. Misunderstanding and negligence in establishing clear specifications are the principal cause of controversy and legal recourse in wheat trade. Items such as protein content need to be specified in terms of moisture basis and whether the required level is an absolute minimum or an average level throughout the shipment. Other quality terms will typically include such factors as moisture content, test weight (grain

density), sprout damage level, typically expressed in Falling number units and dockage or impurity level.

Delivery conditions are another important component of a contract. A seller may quote a price on a free-on-board (FOB) basis, which specifies to the buyer that the seller is quoting on the basis of a loading port. For deliveries on the basis of an unloading port, prices will be quoted on a cost–insurance–freight (CIF) or a cost-and-freight-only (C&F) basis, therefore the seller is looking after some or all of the delivery terms.

In the past there tended to be the need for contract performance guarantees, or some type of performance bond, to ensure fulfillment of the contracted product. Today, where there is a relatively small grouping of buyers and sellers, a letter of credit from the buyer's bank is the principal requirement of the supplier. When a new buyer or seller enters the marketplace, stricter financial credentials are needed.

Major Wheat-Exporting Nations

The movement of wheat from the farmer in one country to the flour mill and processor in another can take many paths. Exporting agencies or marketing boards, private grain traders and importing agencies can all be involved. Where wheat exports are controlled by an agency or a board, they may deal directly with the importing agency or private company and look after all the necessary credit, freight logistics, and certification requirements. Or they may just conduct the sale and hand off some or all of the intermediate activities to private trading companies. Of the 110 Mt of world wheat trade ~31% (Canada and Australia) use export marketing boards and perform a mix of these activities. On the import side, nations that have government importing agencies using public or private tenders account for ~40% of the volume moved. There is a slow trend for importing countries to privatize their wheat import purchasing by eliminating their government import agencies.

United States

The US federal government, through the Federal Grain Inspection Service (FGIS) of the United States Department of Agriculture Grain Inspection Packers and Stockyards Administration, controls the grading standards for wheat and many other grains, oilseeds, and other field crops.

The US wheat grading system encompasses five classes and six numeric grades segregated by different physical properties. For some classes there is further classification by protein content. By law, all export shipments of wheat are inspected by FGIS who issue both official grade and weight certifications.

Table 1 The classes of US wheat, with 5-year average production (1999–2003) and percentage values

Wheat class	*Production (Mt)*	*Percent of total*
Hard red winter	23.62	41.6
Hard red spring	12.41	21.9
Soft red winter	11.09	19.5
Soft white	6.94	12.2
Durum	2.7	4.8
Total	56.76	

Source: US Wheat Associates, 2003 publication (http://uswheat.org).

According to a 2003 publication of US Wheat Associates, the classes of US wheat, with five-year average production (1999–2003) and percentage values, are as provided in Table 1. There is also an emerging "hard white" class that has averaged ~300 000 t of production from 2001 to 2003 and has the potential to grow much larger. This class has been adopted as an official sixth class of wheat in the US system.

New wheat varieties have been developed mainly by state agricultural colleges and universities. Improvement by scientists is guided primarily by the need of farmers for high-yielding wheats that resist drought and disease, but also by end-use quality requirements. Registration of wheat varieties into the various classes is unregulated although there is a peer review system for evaluation of agronomic, disease resistance and end-product quality. Uptake of new wheat varieties by farmers is based on agronomic and disease performance with improvements to quality characteristics being a desirable, but not obligatory, part of the system.

Although the US is considered to operate under totally free market conditions, there are two factors that can influence or distort wheat trade and marketing. First, the US government, as mentioned earlier, is involved in numerous programs and schemes that provide support and subsidies to aid farmers or provide customers with beneficial credit arrangements or discounts. Although controversial and open to debate, there is a general feeling that these programs do not allow world markets to function on a level playing field. The other influence comes from the concentration that exists in the major private grain companies that vie for the farmer's product. As recently as 1998, there was a US Department of Justice investigation into the merger proposal of two of the country's largest grain trading businesses. After the investigation was completed in 1999, Cargill Inc. took over the commodity marketing operations of Continental

Grain and the merger was only approved on conditions of sales of a number of their handling facilities. The government felt that this was necessary to avoid concentration in certain key regions that could lead to fewer marketing choices and lower returns for farmers.

On-farm storage accounts for ~60% of the amount of grain grown in the US; therefore, the majority of farmers must at some point make a choice on moving the wheat to market. When a farmer is ready to deliver wheat there are generally two marketing choices for commercial sale. As one choice, the product can be sold to either a local cooperative or an independent grain company. The second choice for a farmer is to make the wheat available to the government through a wheat loan. In the former case, the farmer negotiates a final price directly with the buyer. If selling through the government wheat loan program, the farmer receives the deficiency payment that has been established by legislation and compensates farmers for marketplace shortfall. In either scenario, the wheat is delivered to the country elevator where the grade is established. Country elevators may also provide drying and conditioning services and may offer a variety of transport and payment terms to the farmer.

Wheat delivered to the government under the wheat loan program can be used by the government to put into the federal Food Security Reserve or for delivery to export customers through the Commodity Credit Corporation. This latter organization authorizes the sale of agricultural commodities to other government agencies and to foreign governments and the donation of food to domestic, foreign, or international relief agencies. The Commodity Credit Corporation also assists in the development of new domestic and foreign markets and marketing facilities for agricultural commodities.

Country elevators, especially those in wheat-producing regions, increasingly ship grain directly to ports, often using large shuttle trains. They also ship by truck or rail to processors, feedlots, and to larger river and rail-terminal elevators. River elevators usually ship grain by barge to port elevators, although their grain may also move to processors. Rail terminal elevators ship to processors and port elevators in large shipments up to 100 rail cars. About 50% of movement of wheat from inland to export position is by barge along major river systems such as the Mississippi.

Export of wheat from the US is from the port facilities of four regions – Gulf of Mexico, Pacific northwest, Great Lakes or through Atlantic ports. Port elevators usually combine grains of different grades, protein levels, and other characteristics to meet buyer specifications, and they may also clean, dry, or condition the grain to meet required specifications.

The majority of sales of US wheat to importing nations is conducted by very few companies. Cargill/Continental together account for 40% of all US grain exports. Exporting marketers operate large overseas networks of elevators and trading offices through which the companies attempt to arbitrage differences in grain prices, buying grain at times and locations where prices are low, and selling at times and locations where prices, net of transport and storage costs, are high.

The US has three major commodity exchanges that deal in futures transactions for wheat, with each trading a separate type of wheat. "Soft red winter" wheat is traded on the Chicago Board of Trade, "hard red winter" wheat is traded on the Kansas City Board of Trade, and "hard red spring" and "white" wheat are traded on the Minneapolis Grain Exchange. There is no commodity exchange that trades durum wheat. In global wheat trade, these three commodity exchanges are used to establish base prices for equivalent wheat types around the world.

Canada

The Canadian Grain Commission (CGC) is the official federal government agency that exercises independent control over quality aspects, class designation and grades, under authority of the *Canada Grains Act*. There are seven designated classes of wheat in each of western Canada and eastern Canada, although they are not identical. Sale of wheat from Canada is most often based on CGC official grade designation with additional grade specification rarely needed. All export shipments of wheat are accompanied by a CGC "Certificate Final," which is a certification of the class, grade, and protein level (where applicable) of the parcel of wheat.

There are two major wheat-growing regions in Canada and production from these is marketed in significantly different ways. In eastern Canada, wheat, principally "soft red winter," is grown in Ontario with smaller amounts in Quebec and the Maritime provinces. The area of western Canada produces a much larger amount, principally "hard red spring" and durum wheats. Table 2 provides the production for 2003, noting that the eastern Canadian production was ~75% greater than normal, due to ideal growing conditions.

Wheat from eastern Canada is generally sold through private traders, with price determination based on negotiation and official CGC grades to meet customer requirements.

Table 2 Production for 2003

Region	Production (thousand metric tons)			
	Winter wheat	Spring wheat	Durum wheat	Total wheat
Eastern Canada	2081.0	365.6		2446.6
Western Canada	751.1	16 074.7	4279.6	21 105.4
Total Canada	2832.1	16 440.3	4279.6	23 552.0

Table 3 Production of seven wheat classes

Wheat class	Production (Mt)	Percent of total
Canada Western Red Spring	20.93	75.8
Canada Western Amber Durum	4.19	15.2
Canada Prairie Spring Red	1.40	5.1
4 minor wheat classes	1.09	3.9
Total	27.61	

Source: CWB, Weather & Crop Surveillance Department, November 2003.

For the 90% of Canadian wheat production from the western region, authority to market wheat on behalf of farmers has been legislated to the Canadian Wheat Board (CWB). All farmers who grow wheat for human consumption for domestic and export markets must market through the CWB. Although wheat grown for domestic feed, seed, and inter-farm trade in western Canada is outside the control of the CWB, any feed wheat for export markets is under their authority.

Production of the seven wheat classes from western Canada for the five-year period 1999–2003 is presented in Table 3.

Varieties within the classes go through a formal registration process, controlled by the Canadian Food Inspection Agency of the federal ministry Agriculture and Agri-Food Canada. Varieties are evaluated for agronomic, disease resistance, and quality characteristics by a committee of experts in the field and must meet functional expectations based on check varieties within each class.

The CWB is controlled by a 15-member board of directors that is two-thirds elected by farmers and the balance appointed by the federal government. The CWB single-desk authority has been challenged on many occasions, especially by US interests, as being nontransparent and outside the spirit of open trade. The debate on this issue continues and the US has been successful in imposing an import tariff on Canadian "red spring wheat" (not durum), although this is being appealed through the North American Free Trade Association (NAFTA) tribunal process.

The CWB determines the available quantity and quality of the various wheat classes soon after harvest and then devises a sales strategy to sell it to customers to make the best return possible for farmers. As sales are made, the CWB acquires ownership of wheat from farmers, paying them an initial price that is set at ~70–80% of the expected return for that quality of wheat for the marketing year. Farmers' wheat is made available to the CWB through a system of delivery quotas and contracts calculated to share market opportunities among farmers and to call forward particular qualities and quantities of grain as required to meet the sale.

The initial price is a guaranteed price by the government of Canada, so even if there is a downward swing in prices, the initial price is protected for farmers. At the end of the crop year, after all sales are made, prices are pooled for wheat and durum; normally, the final realized price is well above the initial price and the farmer benefits from a final payment after the CWB has covered its operating costs. When prices move up significantly through the marketing year, farmers receive interim payments.

About two-thirds of sales by the CWB are made directly to buyers with the balance being sold through an approved list of accredited exporters acting as agents for the CWB. In all cases, the CWB establishes the sales price for the given quantity and quality of wheat to the permitted destination. The CWB is the single desk authority of wheat sales and does not sell wheat to third parties who could then resell to end users.

Farmers in Canada for the most part have sufficient on-farm storage to carry their total production for the year. This gives them the opportunity to move wheat and other field crops into the marketplace at the time that they feel will give them the best value. Farmers contract with the CWB for the specific quantity of each class and grade they produce and agree to deliver a minimum of 85% of that quantity when called for by the CWB to meet sales obligations through the crop year.

Rail movement is the principal means of getting wheat from the primary elevator system to port for

export delivery or to customers within North America. For export, ~65% of wheat is moved to the western ports of Vancouver or Prince Rupert. About 30% is moved by rail to the port of Thunder Bay at the head of the Great Lakes, from where it is transported by lake vessel to terminal elevators in ports along the St. Lawrence River. A small amount of wheat is moved during a brief three-month period out of the northern port of Churchill on Hudson's Bay.

The strong dependence on rail movement for grain and other major commodities in the heartland of Canada has been an issue of political and economic pressure in the Canadian system. A major rail transportation subsidy was removed in the mid-1990s, and railway companies continue to lobby for improved rail transportation rates claiming poor margins in dealing with the vast distances and often harsh climatic conditions in moving product to port. It can cost a farmer more to move grain by rail from his farm in central Saskatchewan to Vancouver than from Vancouver to a flour mill many thousands of kilometers away in South America or Asia. The average distance to move wheat from the western growing region to port facilities is ~1350 km. Producers in the eastern wheat-growing region are much closer to port facilities, averaging ~150 km.

European Union (EU)

There are no formal classes, grading system, or variety registration requirements within the various countries making up the European Union. In some countries there is an approved list of wheat varieties that meet specific functional qualities but even within this loose classification system wheat is generally traded through agreed specification between buyer and seller.

Production of wheat by the 15 member countries of the EU in the ten-year period of 1993–2002 averaged ~93 Mt, making it the second largest wheat-producing region of the world after China. Internal consumption is significant and over the same time period only ~16 Mt annually was available for export. The surplus is purchased by private grain traders and wheat processors or by governments under the EU's Common Agricultural Policy (CAP). This policy establishes minimum quality specifications and, if a farmer's wheat can meet these, the government is required to accept delivery and pay an annually established "intervention" price. Due to the strong farm lobby in EU nations, this price is a major negotiation issue and is calculated to provide farmers with incomes equivalent to incomes in the non-farm sector. Since the intervention price is generally higher than world market prices, the EU is often challenged as subsidizing farmers to a level that distorts world trade.

EU domestic wheat buyers pay prices to farmers that are significantly higher than world prices. This results in a significant level of support from the non-farm sector as consumers are ultimately paying these higher support levels. In addition, for exported wheat the EU budget supports CAP prices to farmers for wheat that brings a lower value on the world market. Agricultural reform within the EU is attempting to modify the support level on a more direct basis rather than through commodity price support but the social, economic, and political pressures provide challenges in achieving this.

Due to the two-price system in the EU, the Brussels government must control export wheat price levels and volumes. On a weekly basis, private trading companies compete for the established EU export program. As the support level changes through agricultural reform, export subsidies are evolving as having less impact in determining export prices.

Very little wheat is moved by rail within EU countries. Due to the relatively short distances to various processors or port facilities, most wheat is moved by truck or by barges through the well developed canal systems of many of the countries.

Australia

Wheat classes, grading standards, and the variety registration process in Australia are highly controlled by AWB Limited (formerly Australian Wheat Board), now a private company that has a government-legislated authority over all bulk export sales of wheat. When a new wheat variety is introduced, AWB designates for which of the seven classes it will be eligible. On an annual basis, AWB establishes receivable standards for wheat to be delivered based on growing and harvesting conditions, crop expectations, and customer requirements. Wheat delivered into the system that does not meet receivable standards for the seven major classes can be graded as Australian General Purpose, Australian Feed or other special designations. AWB's commercial grain testing laboratory provides certification on the quality of export or domestic shipments of wheat.

Average wheat production in Australia for the ten-year period 1993–2002 was 19.4 Mt, with a range of 8.9–24.8 Mt. Production can often be affected by severe drought, with Australia having had devastating drought years in 1982/83, 1994/95, and 2002/03. Due to the small population in Australia, ~75% of wheat production is exported, with average wheat exports of 14.4 Mt for the same ten-year period.

Table 4 Percent by class of receivals, 1998–2002

Class	*1998–99*	*1999–2000*	*2000–01*	*2001–02*	*2002–03*
Australian Prime Hard	5	6	3	5	2
Australian Hard	14	16	3	15	20
Australian Premium White	31	31	34	32	34
Australian Standard White	32	31	26	28	20

Source: AWB Ltd. Crop Reports, 1998–99 to 2002–03.

Although AWB does not publish production or sales by specific wheat classes, their annual crop report does provide an indication of receivable percentages for the major classes, as outlined in Table 4. The other wheat classes include Australian noodle, Australian soft, and Australian durum.

AWB operates in a manner similar to the CWB in Canada; however, there is one very important distinction here, and that is, since privatization, AWB no longer benefits from government underwriting or any other form of support. Within Australia, there is a "dual market" system as domestic processors can buy wheat either from private traders or through AWB. Also, bagged or container sales of wheat to export markets can be made through private traders.

Farmers have a choice of various innovative pricing options when they make their wheat available to AWB. These include pricing on the wheat futures market, foreign exchange market, or on the basis of contracts. All of these are self-managed options for the farmer. Farmers may also accept a simple pooled pricing formula that gives them 80% of the expected pool price upfront and a final payment after all sales are pooled.

AWB direct sales to buyers represents ~70% of all wheat sales. The balance of sales are made through approved grain trading partners. Farmers deliver wheat to local Bulk Handling Authority (BHA) storage facilities. These complexes used to be mainly farmer-owned cooperative facilities but many of them have now privatized. AWB has recently become a competitor to the BHAs, as they have built their own storage facilities. Since there is limited farm storage, representing only ~9 Mt capacity from a total grains production of 41 Mt, the majority of wheat is moved directly to a BHA after harvest. At delivery, the receivable standard grade is assigned and the farmer chooses the pricing option desired.

The wheat-growing region in Australia follows the coast line in a crescent around the east, southeastern and western coasts and the average distance from production regions to port being ~350 km. Wheat is moved from BHA storage to export position by truck or by rail as called forward and needed by AWB's sales program.

Argentina

The Ministry of Agriculture in Argentina introduced a grading and classification system in the late 1990s. There are three classes, plata, prime, and "soft winter" and each is graded into four quality levels. The ministry also controls the registration system to ensure that new varieties meet quality expectations as well as agronomic and disease resistance attributes. For export wheat shipments the ministry also issues grade certification, verifying conformity with the established grade standards.

Until 1991, all wheat marketing was under state control through the National Grain Board (NGB). The NGB had significant wheat storage facilities, both inland and at port positions that were subsequently sold off to farmer cooperatives or the private sector. Wheat production increased with deregulation of the agricultural economy and elimination of the NGB and wheat export taxes. In the early 1990s, wheat production averaged under 10 Mt per year but from 1998 to 2002 production increased to an average of 14.4 Mt. This has allowed Argentina to increase wheat exports and it is currently the fifth largest exporter, with average exports over the last five years of close to 10 Mt. Since Argentina is in the Mercosur trading agreement along with Brazil, Uruguay, and Paraguay, these countries, principally Brazil, account for ~65–70% of Argentine wheat exports. The Mercosur agreement is a protectionist umbrella for Argentine farmers as wheat from origins outside the Mercosur countries must incur significant tariffs, which are used to compensate Mercosur farmers. Since Argentina is by far the largest wheat producer in the region, their farmers get the most advantage of this system.

On-farm storage is minimal in Argentina and wheat competes strongly with other important crops, especially soybeans and maize, for commercial storage space. This means that farmers can often be forced into "price to be fixed" contracts in order to take advantage of exporters' and millers' storage facilities. In addition, farmers in Argentina tend to have a much poorer working capital level relative to those from the other major exporting nations and access to credit is

limited. This puts farmers at a disadvantage when negotiating prices at harvest time and there tends to be a lot of pressure for exporters to make sales close after the harvest period in order to maintain turnover in storage facilities. In Argentina the harvest pressure occurs generally in March, which is outside the time range of harvest availability from the other exporters from late summer to early winter (July–December). Demand tends to come from non-Mercosur destinations, especially those that have lower quality expectations, such as Iran, Iraq, and African nations.

The rail transportation system in Argentina is in poor repair, having been built in the nineteenth century by British, French, and German interests, with each system having incompatible track gauges. Therefore, truck transport is most often used to get wheat from the growing regions to port. The average distance from country position to an export port is ~300 km. There is also use of barges and ships along the major Parana river system, with continuing effort to increase draft levels to allow larger ships to move further inland.

Minor Wheat Exporting Nations

During the early 1990s through early 2000s, the major exporters have accounted for trade as presented in Table 5.

It is significant that the "others" category has increased over the last two crop years, mainly due to poor growing and harvest conditions for the traditional exporters and bumper crop conditions in other parts of the world. This includes countries and regions such as Russia, Kazakhstan, Ukraine, Eastern Europe (Black Sea exporters) as well as Pakistan and India. Over the last two calendar years (2001–2002) even China was entering the export market for wheat. These countries have traditionally been self supporting and only tend to enter the world trade arena in a minor way. Surpluses in the last two years accompanied by shortages from the traditional exporters have resulted in the private grain trade moving wheat from unusual origins to service need around the world. Importers have needed to review their quality expectations and blending capabilities as wheat has come from nontraditional sources. The infrastructure of minor wheat exporters has been challenged by the huge amount of wheat and other grain that has moved through their system.

It can be expected that these regions of the wheat-growing world will continue to make improvements in transportation and storage infrastructure as well as grading and quality selection in order to be able to command increasing share of world trade. Traditional exporters will need to respond to the challenge from these newer exporters by improvements in their own marketing strategies, perhaps turning away from lower value "commodity" wheat and toward supply of higher value, identity preserved selection of wheat types that meet specific end-use functional quality.

Conclusion

The various wheat marketing systems of the major exporters have been presented, showing there has developed a well-recognized and traditional international trading environment that is affected by geo-political influences. Governments can have a significant impact on trade characteristics, especially where subsidies allow farmers to produce products that would not normally be grown if the subsidies were not available. Recently, newer players have entered the wheat marketing environment and created

Table 5 Exports of all wheat, semolina, and flour by principal exporters, 1993–94 to 2002–03 (July–June) (thousand tonnes and percentages in parentheses)

new opportunities for importers and challenges for traditional exporters.

Wheat remains a major food source and is a unique agricultural product due to the vast range of consumer products that can be produced from it. As developing nations improve their economies they can be expected to demand a greater variety of foodstuffs and wheat will become a greater part of their diet. This is expected to increase world trade in wheat as these nations do not tend to be traditional producers. The dynamics of wheat marketing systems around the world will have to develop to meet this new demand.

Introduction

Starch produced from wheat was identified as a binder and stiffening agent early on; it was used in the making of historical textiles and paper-made utensils in Egypt and Greece. J. Beccari developed the first aqueous process for the separation of starch and gluten in 1745, this formed the basis for modern technology. Wheat starch has had an unparalleled use for purposes of stiffening and finishing until modern times. However, the introduction of starches from potatoes and especially from maize in the course of the last century diminished its importance significantly. Utilization of wheat starch was reduced mainly to application in food, in particular, for baking purposes. Political decision making of the European Community in the 1990s drastically changed the situation again. Modern production of wheat starch is closely connected with its most important dried co-product – vital dry gluten. This product consists of water-insoluble high-molecular-weight protein particles, which are able to recreate the viscoelastic structure typical for wheat flour dough. In many countries worldwide, only beneficial commercialization of vital dry gluten enables economic production of wheat starch.

Based on figures presented in 1999, a valuable estimate for the actual situation can be given (Table 1).

As a result of different economic reasons and requirements, wheat starch and gluten production show significant imbalance in size in different world regions. The indisputable leading position of the European community (approximately two-thirds of world production) is followed by the Americas and the Asian and Pacific area with about one-third of total production, both with an equivalent ratio. Eastern Europe, in comparison, plays a minor role.

In Europe wheat starch is traditionally used in confectionery production, but substantial amounts are converted to sweeteners. More recent developments allow for utilization in various sections of nonfood industry too. Dry vital gluten is a substantial product in fortification of low-protein flours, but is also used in production of pet food and aquatic food. The advantage of this product results from the ring- or flash-drying process that retains its functional properties

Table 1 Worldwide production of wheat starch and gluten by regional distribution

Region/production (10^3 Mt)	*Starch*	*Gluten*
European community (8 of 15 countries)	1964	373

and allows the characteristic viscoelasticity to return when rehydrated.

Technological Developments

Developments in starch extraction from wheat were the result of numerous variations in process engineering. Wheat kernels as well as wheat flours of differing composition have been used as raw material. The indicated processes allowed recovery of the main wheat components – A starch, B starch, and gluten– in different quantity and quality. Protein extraction from kernels produced only in few processes the water-insoluble wheat protein fraction as the high priced and therefore interesting vital gluten. Finally, those processes that yielded the high-quality vital dry gluten from wheat flour were successful.

Changes in process engineering, in particular the switch from the original flour-based dough systems to dispersions of varied dry substance concentration, found their expression in the selection of respective source materials. In dough-processing techniques, like the once-popular Martin process, protein-rich and strong gluten-producing flours were in general prerequisites with respect to satisfying dough formation and successive extraction by intensive and water-consuming washing procedures. In contrast, in Europe recently introduced processes are based on differentially defined centrifugal separation techniques, allowing use of wheat flours of reduced protein content and protein quality as well. In this respect, even softer wheat cultivars can be applied in starch factories that must ascribe to the limiting range between bread wheat and feeding wheat. This situation allowed a favorable adaptation to market developments, where gluten prices especially could no longer contribute in the usual manner to the necessary revenue of wheat starch production.

In 1999, Maningat and Bassi presented an overview of the state-of-the-art wheat starch production. Their presentation highlighted the situation in the Americas in particular, where the modified Martin, hydrocyclone, Alfa-Laval/Raisio, and the Westfalia three-phase decanter processes are standard procedures in the industry. In contrast, technologies based on high-pressure agglomeration of gluten-forming proteins and three-phase decanting (Westfalia process) or the modified Martin process, were indicated as predominant in European industry. Another alternative exists with the Tricanter® process. Driving in process development was the necessary reduction in fresh-water consumption in relation to wheat flour (Table 2). The consumption occurs as water is used for dough or batter preparation, as well as in the following extraction/separation of starch, gluten, fibers, and further components. While a water/flour ratio of up to 15 : 1 was applied for the Martin process in its traditional form, the modified Martin process as well as the batter process required less than half the quantity of water consumed earlier. Technological improvements and consistent recycling of process water led to this important reduction. At the very beginning, a concentrated flour–water system, similar to a baker's bread dough, is prepared for extraction. For other process proposals, which used hydrocyclones or decanters as primary separations systems, further reductions in the ratio of flour to water were reported. In more recent developments such as the Westfalia process, which represents efficient lump-free hydration of flour particles, mechanical agglomeration of gluten forming proteins by application of high pressure, and downstream three-phase separation in a decanter, the procedures induced further reduction towards a minimum ratio of approximately 2.1 : 1.

Table 2 Water/flour ratios requested according to process variants in wheat wet milling

Technology	*Water/flour ratio*
Martin process	15 : 1
Modified Martin process	6 : 1
Batter process	5–7 : 1
Hydrocyclone process	4–5 : 1
Decanter process	4 : 1
HD/Westfalia	2–3 : 1

They also described in detail the modified Martin process, the hydrocyclone process, and the Alfa-Laval/Raisio process as reported by Bergthaller and Kersting. For decisive improvements in process technology, only effective water regime will not suffice. As there are substantial developments in initial flour hydration and subsequent separation of components from each other in early stages of a selected process unit operations are necessary.

Obstacles of Wheat as Substrate

Starch Particle Size Distribution/B Starch

Scanning electronic microscopy of wheat flour particles (Figure 1) illustrates the central problem of isolating the starch from other flour constituents. Besides the main portion of big-sized granules, many tiny granules are visible and all of them are closely embedded in a matrix composed essentially of protein particles. Following the characteristic particle size distribution of wheat starch that can be described as bimodal (Figure 2), in wet milling the starch is classified into two products, high-grade starch (called A

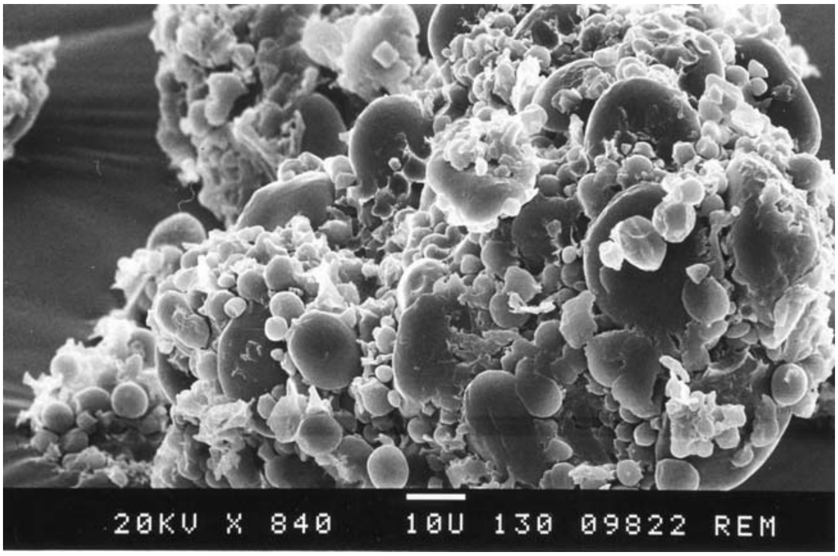

Figure 1 Scanning electron microscopy of starch granules and protein bodies embedded in cells of a flour particle.

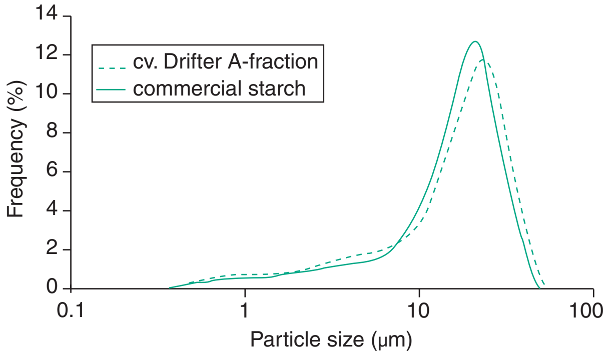

Figure 2 Wheat starch particle size distribution.

Table 3 Upper limits for impurities of commercial wheat starch according to general quality requirements

Criteria	*A Starch*	*B Starch*

Minerals (% i.s.)	0.3	1.0
Lipids (% i.s.)	0.1	0.5
Sulfur dioxide (mg kg^{-1} i.s.)	50	50

[a]N conversion factor = 6.25.

starch, as it comprises big-sized granules for the most part) and lower-grade starch (commonly called B starch or "tailing" starch, which mostly consists of small granular starch (SGS)). This fraction contains so far granules that are associated in general with bigger amounts of proteins, lipids, and pentosans. The much higher specific surface area of B starch granules and resulting differences in classifying, washing, concentrating, and drying make it particularly difficult in processing them further.

As a result of processing, commercial wheat starch products differ significantly in purity. Their quality requirements are described in general by criteria represented in Table 3.

Pentosans

Another group of grain components, the pentosans, causes serious problems in wet milling of wheat flour. The main and most disadvantageous property with respect to starch separation is the extreme water-binding capacity that seriously changes the viscosity of suspensions. The pentosans represent water-soluble and water-insoluble arabinoxylans of differing molecular weight. The presence of this fraction results in a reduced recovery rate of gluten, due to an incomplete agglomeration of gluten. Furthermore, impeded separation of fractions is induced during initial centrifugal operations applied to water/flour suspensions as well as classification steps in mill starch streams. High concentration of pentosans neutralizes differences in density and particle size. Existing differences cannot contribute effectively in relevant separation procedures.

A potential application of pentosan-degrading enzymes in wheat wet milling, xylanases, is to break down pentosans in order to reduce viscosity of flour slurries.

Modern Wet Milling Processes

The Modified Martin Process

The modified Martin process, the modern variant of the traditional procedure after necessary improvements and modifications, still exists for wet milling of wheat starch worldwide. Necessary improvements were for the most part a result of reducing freshwater consumption through increasing process water recycling to the maximum acceptable extent. Process modifications concerned in general the substitution of equipment towards more efficient separation of starch and gluten. The modified Martin process is described in detail by the flow diagram presented in Figure 3.

Flour milled in the factories or purchased from outside according to local potentials is mixed in a continuous mixer with water to a stiff dough in order to develop the gluten proteins. Water temperature is preferably set at 32°C (90°F). Mixing results in a cohesive dough that is allowed to rest for completion of hydration of flour particles and gluten, in particular. The fully developed dough is then mixed vigorously with additional water under turbulent agitation to accelerate segregation of viscoelastic gluten mass from suspended starch. Separation of gluten from milky starch suspension is done while pumping the mixture into a gluten washer constructed as a long, slanted rotating cylinder equipped with 40 mesh screens. Through nozzles, water is sprayed onto gluten and screens to wash away starch from the gluten and to prevent plugging of the screen. Then, gluten is conveyed to a gluten washer where it is mixed with excess water to remove residual starch. The purified, viscoelastic gluten mass is dewatered and after remixing with dry gluten powder, it is reduced to small pieces of suitable size and is sent for a quick final drying in a flash drier. Drying conditions are adapted to maintenance of maximum vitality, which means instantaneous recovery of viscoelastic behavior when hydrated. After fine grinding, dry vital wheat gluten is till today an economically important by-product of wheat wet milling used for ~80% in flour-mills and bakeries for flour improvement.

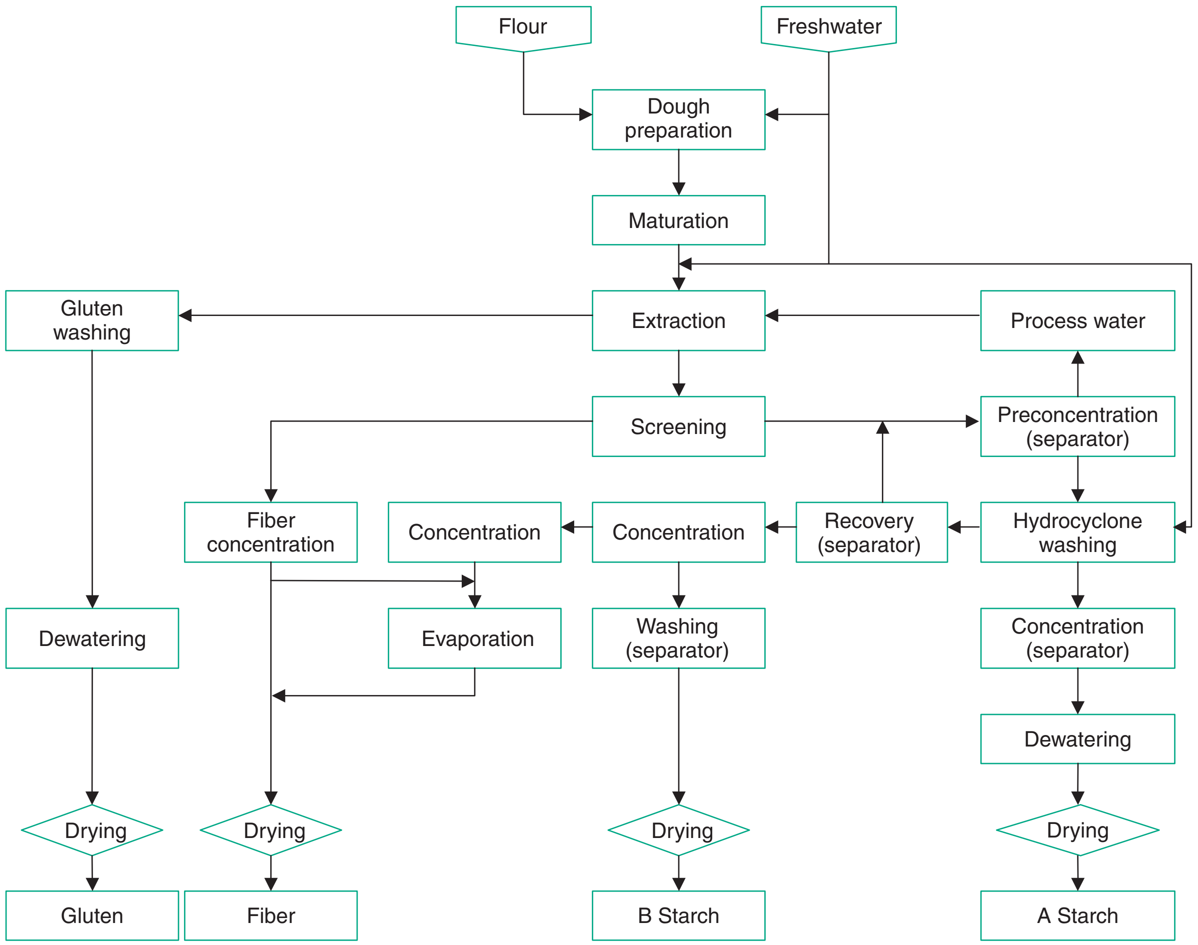

Figure 3 Flow scheme of the modified Martin process.

The starch suspension (starch milk) coming from gluten separation goes through a purification process consisting of a succession of sieving, centrifugation, and hydrocyclone washing. First, small gluten particles are removed by a rotating sieve, shaker sieves, or sieve bends. Bran particles, fibers (mainly of cell wall materials), and gritty endosperm pieces are removed, too. The resulting starch suspension is refined further in nozzle centrifuges where small-size starch (B starch), soluble components consisting mainly of soluble carbohydrates (pentosans and sugars), proteins, and minerals are removed with the overflow. A starch is concentrated the same time to $\sim$35% and leaves the separator via nozzles. Final purification in a counter-current washing process is accomplished using a multistage hydrocyclone system that concentrates starch solids to 40%. After dewatering by means of vacuum drum filter, peeler centrifuge, or alternatively pressure filtration (with 60% starch solids), the starch cake is dried in a flash or drum drier.

The Hydrocyclone Process

A new direction in starch/gluten separation was set with the use of hydrocyclones. Initial stages resemble the modified Martin process. Then, the water/flour dough is conveyed to a maturation tank for 10–20 min of rest and afterwards fed into a dilution tank. There, the dough is mixed with excess water to produce a homogeneous suspension. While passing through a multistage hydrocyclone system, the applied shear induces spontaneous agglomeration. In the hydrocyclone process, separation of agglomerated gluten from starch results from even small density differences between both components. The addressed densities differ, with $1.05-1.1\,\mathrm{kg\,l^{-1}}$ for agglomerated gluten and $1.4-1.5\,\mathrm{kg\,l^{-1}}$ for starch. Gluten is collected together with B starch as the lighter portion in the first section of the multistage hydrocyclone system (in general four stages) as overflow, then purified from B starch, bran, and fibers (cell wall materials) by washing and sieving. After dewatering, gluten is dried. At the same time the starch stream undergoes counter-current washing and purification in an eight-stage hydrocyclone system and before final concentration (up to 40%), residual bran and fiber particles are removed by two-step sieving, for example, through a 75 μm sieve bend and a 50 μm rotating screen. The starch slurry is dewatered then and the resulting cake dried as indicated with the modified Martin process.

The Alfa-Laval/Raisio Process

With introduction of the Alfa-Laval/Raisio Process, which was developed on the basis of a thick wheat flour/water batter instead of dough, centrifugal separation represented by a decanter-type centrifuge was introduced as a new principle. The batter is first treated in a disk-type disintegrator to achieve a homogeneous suspension that is separated then into a starch fraction having a protein content of $\sim$1% and a gluten fraction of $\sim$40% protein. Fine fibers are removed by sieving the starch fraction over rotating conical screens, and final purification and concentration to 55% solids occurs by washing in counter-current mode in subsequent decanters. Drying in a flash or drum drier results in starch of high purity (0.3% protein). Gentle stirring matures the gluten fraction and highly agglomerated gluten is formed. For completing agglomeration, gluten is disintegrated again and vibration screens separate gluten lumps formed once more from residual starch and bran particles. Wet gluten is dried as usual to receive vital wheat gluten. The filtrate coming from the gluten screen still contains B starch, some A starch, and soluble substances (pentosans). While A starch is recycled, all insoluble residues, in particular B starch, are first collected via decanting. B starch is concentrated, dewatered, and dried.

Westfalia Three-Phase Process or Tricanter Process

In successful recent processes, centrifugal separation of starch and gluten in decanter machines is combined with previous rigid segregation of wheat flour into its components – starch, gluten strains, fibers, and pentosans. The application of high pressure with a homogenizer proved to be a very effective prerequisite for splitting flour components in a three-phase decanter. There, mechanical strain, shearing forces, friction, and cavitation produce tissue disruption within the specific valve of a homogenizer. The technique was successfully taken over from studies of improved maize starch extraction after pretreatment of ground, de-germinated maize. By application of this technique ahead of decanter separation, specific wheat protein fractions, in particular the high molecular gliadines and glutenines, are prepared to agglomerate finally to voluminous aggregates. Separation into distinct and characteristic layers (starch, gluten, pentosans, and process water) and its efficiency as investigated in spinning tests strongly depend on the time of rest after homogenization ($\sim$16 min) (Figure 4). Because of the lower density compared to starch, gluten agglomerates leave decanters primarily with lower density phases in the middle phase.

The principal process of continuous preparation of highly concentrated flour/water slurry and its separation into three distinct phases by applying three-phase

decanters exists in varied designs and different distributions. The dominant processes applying this principle are Westfalia process, Flottweg Tricanter process, and Decanter-based Weipro process (Figure 5). In most modern versions, the concentrate leaving the decanter consists almost entirely of A starch (less than 1% protein). Recovered concentrates are further processed by screening, multiple washing, and concentration. Washing and concentration is then realized in a combination consisting of a centrifuge and a multiple stage hydrocyclone unit or a sequence of three-phase separators to produce commercial grade wheat starch (protein content ~0.3% d.b.). The middle phase consists of gluten, SGS, tailings, and some fiber. Gluten is recovered from this stream by rotary or bend screens, subsequent washing in a gluten washer, dewatering, and air drying. The filtrate coming from gluten separation consists, in general, of some SGS, the main part of tailings. The A starch is recovered and added to the main A starch stream for improvement of the recovery rate. Sieving over rotary cone screens or horizontal vibration sieves of adapted mesh size separate fibers and B starch from one another. The B starch stream is then concentrated and dewatered and finally dried by application adapted drying procedures, e.g., drum drying to receive a pregelatinized product. The light phase contains mainly pentosans and soluble compounds and depending on agglomeration potential eventually some finely distributed gluten. The latter

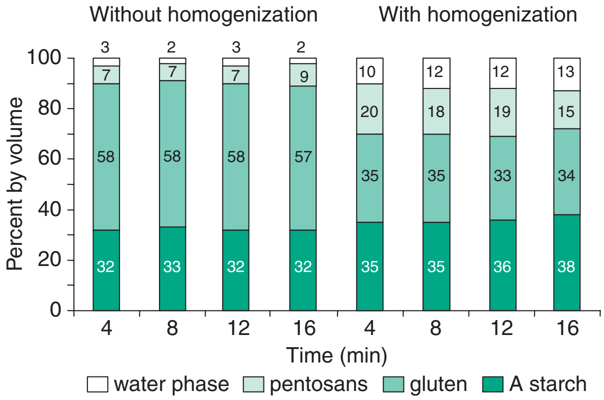

Figure 4 Effect of homogenization and maturation time on gluten formation and separation efficiency after centrifugation of a pretreated and diluted flour/water mixture (determined by percent volume distributions of its fractions.

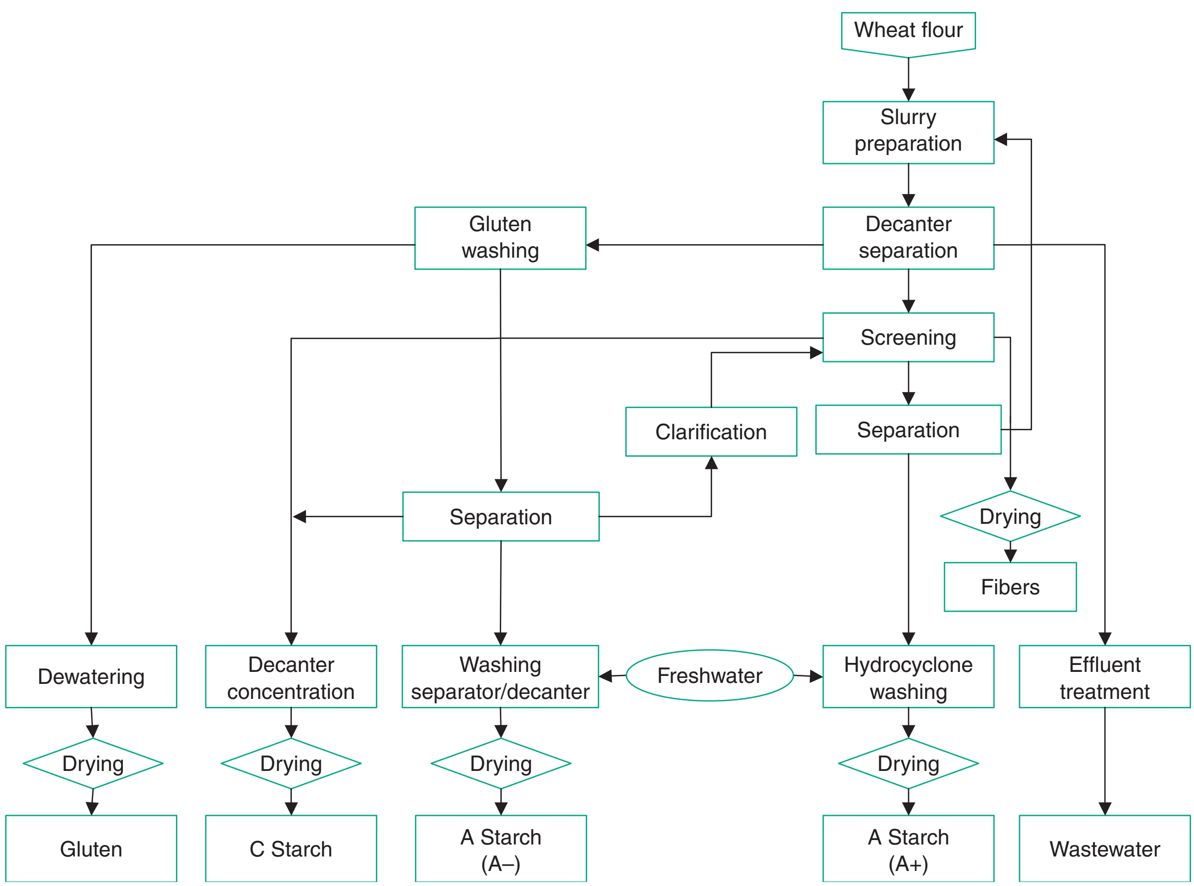

Figure 5 Flow scheme of the Westfalia process for wheat wet milling.

is recovered by filtering the third phase through fine screens. Pentosans can be used as liquid or dried products in animal feeding. In this respect, bran can be mixed with concentrated process water and soluble material together with pentosans in preparing high-value feed. Such products are known as wheat gluten feed and may have protein contents between 17% and 21%.

The Westfalia separator three-phase decanter process designed in the early 1980s underwent various improvements to reduce, in particular, the water regime and recover SGS as A-minus starch. Instead of B starch, a C starch fraction is produced. The new concept is strictly based on the use of three-phase decanters for principal separation of concentrated flour/water mixtures into three phases as described previously and following processing, classification, and washing with three-phase nozzle separators. This concept is described, in principle, in Figure 6. However, even this standard will be further developed to find an even more economic solution.

Selection of Wheat for Wet Milling

Substrate selection refers to grain and flour characteristics as well. The suitability of wheat flour nowadays focuses more on flour data. The selection is based on applied technology and potential recovery rate, in particular, the level of protein, which determines the yield of the most important by-product, dry vital gluten. Two principal technologies are presently applied and they require different demands.

Wheat Grain Characteristics

Specifications widely used in the past for grain indicate a minimum protein content of 12.0–12.5% on dry substance as the key factor in evaluation of suitability. As for wheat, in general, the nitrogen conversion factor is 5.7. Falling number and amylograph consistency ought to reach medium to high level, while endosperm hardness should be low. Falling number and amylograph consistency describe mainly the integrity and quality of starch but also the enzyme status present in grains. Endosperm hardness is closely connected with grain behavior in milling. Greater softness offers not only potential cost reductions in the milling process but also increased A starch yields and reduced starch damage as a result of less pronounced breakage and deformation. Besides the already mentioned characteristics, general requirements for milling wheat ought to be adequate, in particular, its sanitary status and limits for the presence of besatz.

Wheat Flour Characteristics

Processing ability of flours was evaluated analytically in the context of the initial principle in separating starch and gluten. Following conditions of the Martin process, Schäfer described a laboratory procedure for the first time that allowed selective separation of the

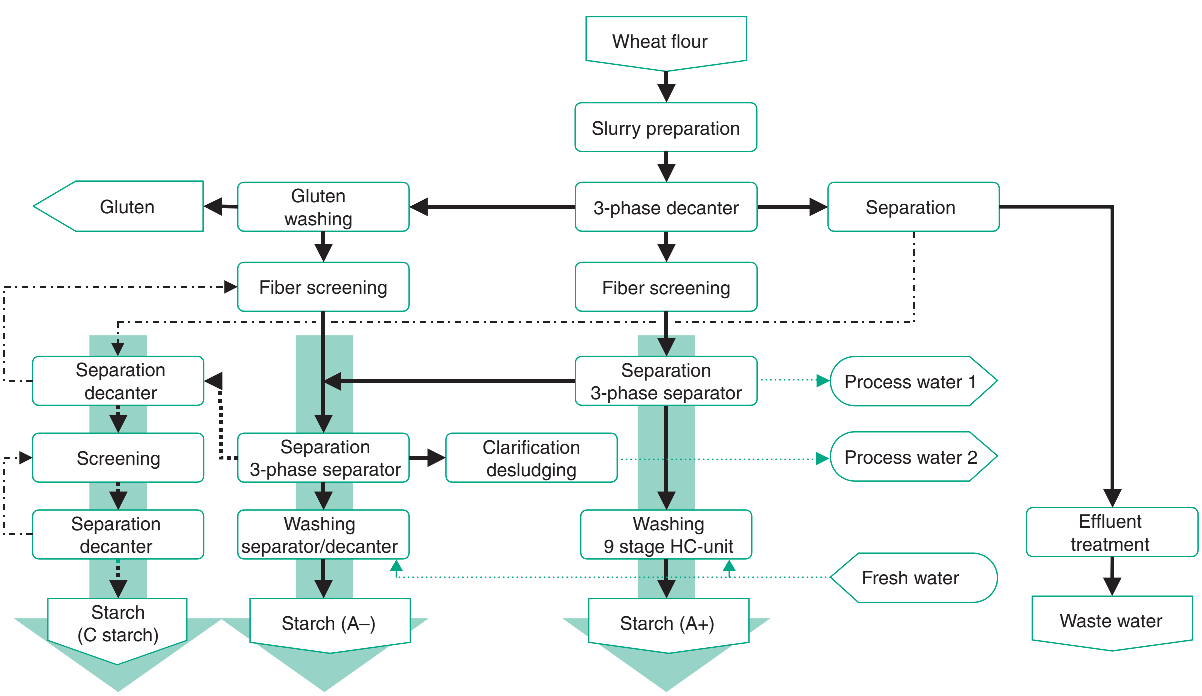

Figure 6 A new concept for A starch and small-size granular starch (C starch) recovery according to a modified Westfalia process.

Table 4 Extended catalog of requirements for wheat flour properties relevant in modern starch manufacture

Moisture	~15.0

main products similar to common wheat wet milling and, finally, evaluation of the flour's wet milling potential.

Diverse corresponding testing procedures were developed on a small-scale basis for identification of new suitable varieties, which use high-speed mixing in imitating mechanical strain and shearing forces applied in decanter processes. Tests of this kind (e.g., the mixer/wash test analysis) allow yield evaluation of moist gluten, dry gluten protein, total dry starch (in case of additionally desired information, split into A and B starch), fibers, and soluble material. However, a spinning test administered as a quick procedure may provide suitable information about separation ability of wheat flours into distinct layers of starch, gluten, pentosans, and process water.

Based upon previously fixed characteristics and extended by additional quantities, Table 4 presents a new catalog of wheat flour properties as optimum requirements relevant for modern starch manufacture. The key information is represented by the amount of recoverable granular white starch based on wheat flour dry substance and addressed here as "starch potential."

Outlook

A new development in wheat wet milling concerns production of organic gluten and starch. Targeting organic products requires specific efforts in providing the concept of identity-preserved products, which deals first in receiving suitable substrates from organic production and second in applying a process that replaces biocides used for maintaining hygiene by rigid cleaning systems. Today sulfur dioxide is still the common biocide in use for suppression of microbial growth and maintenance of process security. In contrast, application of cleaning systems means regular interruption of today's continuous production which functions 7 days of the week, throughout the year. During interruptions, the alternative measure uses intensive cleaning cycles lasting several hours, as this is the practice in manifold food production processes. This expensive alternative procedure produces starch and gluten of a high hygienic standard.

Besides, production of organic gluten and starch requires wheat varieties with a high protein quality. In Germany, maximum level (E-quality grade) or high levels of A-quality grades guarantee, in general, satisfactory expression of high molecular gliadin and glutenin proteins as prerequisites of adapted segregation of starch and protein and agglomeration of protein bodies in initial steps of modern production. Processing ability of flours can be tested by small-scale extraction procedures based on centrifugal separation of high-speed mixed water/flour systems.

Ultrastructure of the Grain, Flour, and Dough

S T Grundas, Institute of Agrophysics, Lublin, Poland
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The wheat grain is unique. Only wheat flour is capable of producing dough with rheological properties that permit the baking of leavened bread. These properties are also needed for the many other food products made from wheat, namely, noodles, pasta, Chinese steamed breads, Arabic flat breads, pastry products, cakes, and cookies. All these products are distinct in the grain-quality characteristics needed for their production. For these reasons, international trade in wheat involves a wide range of wheat grades, each suited to specific groups of food product.

These unique aspects of wheat quality make it a special product in its marketing and processing. As a result, wheat has become much more than a bulk commodity. It has become an object of intense research activity, the "prize" being knowledge about the structure, composition, and function of the grain that can be applied to increase the market value of specific types of wheat.

The resulting knowledge includes insights into the physical structure of the grain and of dough at the macroscopic and microscopic levels. This knowledge has obvious applications in flour milling and in baking, with respect to the respective ultrastructure of the grain and of dough. These aspects of research outcomes are described in this article.

The Anatomy of the Wheat Grain

External Features

The wheat grain is botanically a single-seeded fruit, called a "caryopsis" or "kernel" (Figure 1). It develops within floral envelopes (the "lemma" and "palea"), which are actually modified leaves. Viewed from above (the dorsal side – the same side as the germ), the grains of different varieties may appear to be oval, ovate, elliptical, elongated, or truncated (short). These characteristics can be useful in attempting to identify varieties by aspects of grain shape. In addition, dimensions may be helpful, but they vary with growth conditions. The wheat kernel averages ~2.5–3.0 mm thick (or high as it stands on its base), 3.0–3.5 mm wide, and 6.0–7.0 mm in length. Wheat kernels average ~30–40 mg in weight.

Wheat kernels are rounded on the dorsal side, with a longitudinal "crease" (a deep groove) running the full length of the ventral side. The shape of the groove is a characteristic feature of some species and varieties. The presence of a wide and deep crease is undesirable, because it contributes to making a low bulk density (test weight) for the grain. The main inner volume of the grain is taken up by the starchy "endosperm," which becomes the white flour that is released and crushed to fine particles by the flour miller.

The "embryo" (called the "germ" by millers) forms an irregular patch at one end of the dorsal side of the kernel, near the point of attachment of the kernel to the plant. This point is called the "hilum." The tip of the opposite (distal) end of the kernel is covered with small hairs ("trichomes"). This feature, known as the "brush," can also be a useful varietal characteristic, as wheats may differ in the length of the brush hairs. Several other features of the grain's anatomy are illustrated and labeled in Figures 1 and 2.

The Bran

The wheat grain is enclosed in a series of layers, collectively called the "bran" (Figure 2). This layer is visible by light or scanning electron microscopy as the outermost collection of cells surrounding the grain (Figures 3 and 4). The fluorescence micrograph of Figure 5 shows a section of the bran layers that has become separated from the underlying aleurone-cell layer.

The "pericarp" (fruit coat) surrounds the entire seed and consists of two portions, the outer pericarp

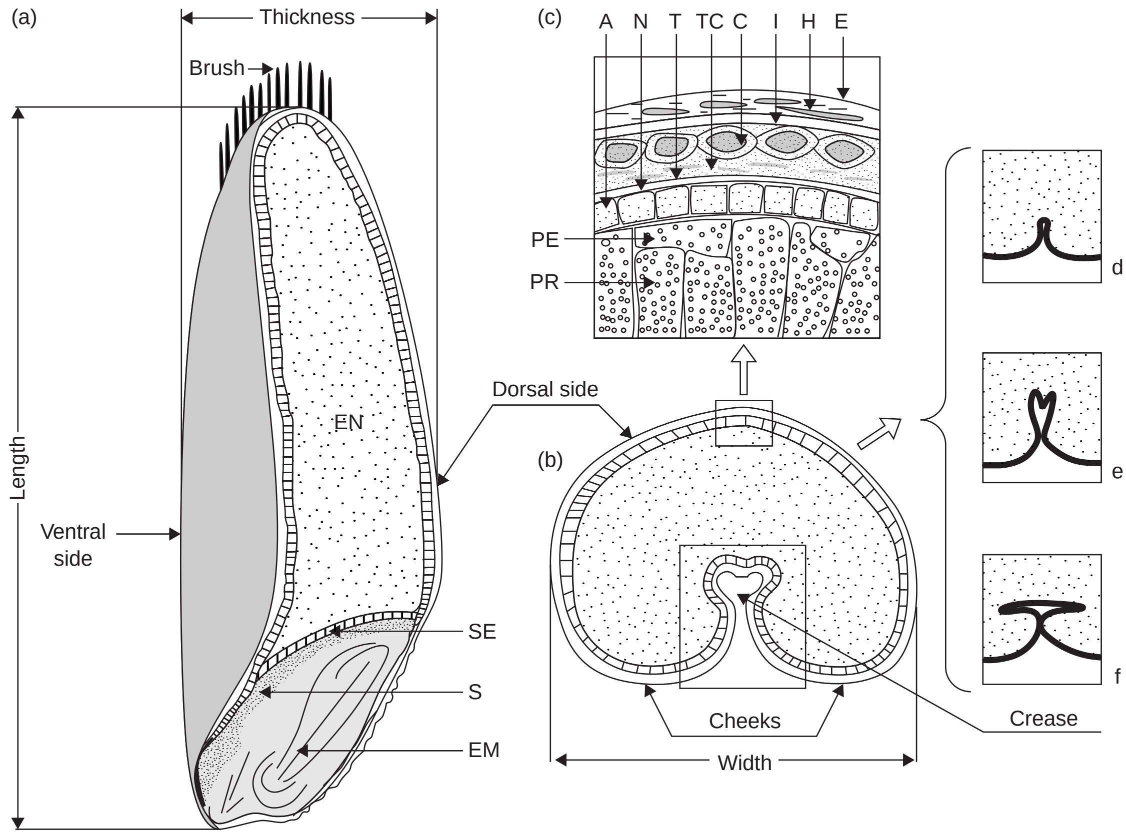

Figure 1 The main morphological components of the wheat kernel: (a) longitudinal section of kernel; (b) cross-section of kernel; and (c) segment of bran layer with aleurone and endosperm cells. Abbreviations to segment (c): E, epidermis; H, hypodermis; I, inner pericarp; C, cross cells; TC, tube cells; T, testa; N, nucellar layer; A; aleurone layer; En, endosperm; PE, peripheral cells of endosperm; PR, prismatic cells of endosperm; SE scutellar epithelium; S, scutellum; E, embryo; d, e, and f, segments with typical shape of creases. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 6139, Elsevier Ltd.)

and inner pericarp. The outer pericarp has the following layers; the "epidermis" (epicarp), the "hypodermis," and the innermost layer, called the remnants of thin-walled cells. These thin-walled cells, which have a discontinuous cellular structure, form a natural plane of cleavage. Removal of the outer pericarp, which millers call "beeswing," also aids movement of water into the kernel. The inner pericarp, adjacent to the remnants, is composed of intermediate cells – a single layer of cross cells and tube cells. The cross cells are long and cylindrical ($\sim 125 \times 20\,\mu m$), and have a long axis perpendicular to the long axis of grain. They are tightly packed, with little or no intercellular space.

The tube cells are similar in size and shape to the cross cells, but they have their long axis parallel to the long axis of grain. The tube cells are not packed tightly and do not form a continuous layer; thus have many intercellular spaces. They are only recognizable in the mid-dorsal region of mature grains. The next layer inwards is the seedcoat ("testa" or "integument"), which is firmly joined to the tube cells on the outside and the nucellar epidermis on the inside. The seedcoat of red wheat consists of a thick outer cuticle layer, which is strongly pigmented, and a thin inner cuticle layer. The seedcoat in white wheat has cell layers containing little or no pigments. Grain color, usually red or white (although purple is also known), is related to pigment in the testa.

Tightly bound to the internal surface of the seedcoat is the nucellar epidermis ("hyaline layer," "perisperm"). The thickness of the seedcoat varies from 5 to $8\,\mu m$. The nucellar epidermis is $\sim 7\,\mu m$ thick and closely attached to both the seedcoat and the aleurone layer. The total pericarp has been reported to comprise $\sim 5\%$ of the kernel volume.

The "aleurone" layer, which is generally one cell thick in wheat, completely surrounds the kernel, covering both the starchy endosperm and the germ, except for that adjacent to the scutellum (Figure 2). Although the aleurone layer is anatomically a part of the endosperm, the miller regards the aleurone as the innermost layer of the bran. The majority of the mineral matter located in bran is found in the

aleurone layer, which also contains one-third of the grain's thiamine content. The cytoplasm of the cells contains many small (3–4 μm), round aleurone granules surrounded by lipid droplets.

The aleurone granules contain two types of inclusions: type I contains phytin and type II contains protein, carbohydrate, and bound nicotinic acid, which is largely unavailable for human nutrition. The phytin granules are the main source of mineral matter. Hence, the degree of aleurone (or bran) contamination of flour is frequently evaluated by an ash analysis. In addition, thiamin and riboflavin are higher in the aleurone layer than in the other parts of the bran, and enzyme activity is high. Over the embryo, the aleurone cells are modified, becoming thin-walled cells that may not contain aleurone granules. The thickness of the aleurone layer over the embryo averages ~13 μm, or less than one-third the thickness found elsewhere. The aleurone cells are heavy-walled, essentially cube-shaped, and free of starch. They can vary in thickness from 30–70 μm within a single kernel and have thick (6–8 μm), double-layered cellulosic walls.

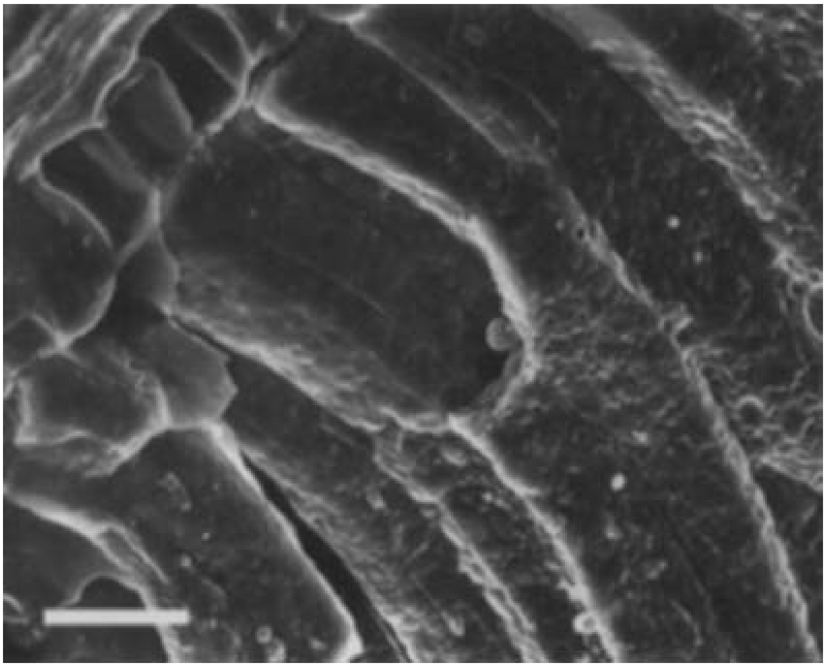

Figure 4 Scanning electron micrograph of the cut surface of a vitreous kernel of wheat, showing the subaleurone region with peripheral and prismatic cells. Note that a fracture has taken place at the interface between the cell contents and endosperm cell wall. The length of the bar at the lower left is 50 μm. (Reproduced with permission from Grundas S (ed.) (2003a) Wheat: grain structure of wheat and wheat-based products. In: *Encyclopedia of Food Science and Nutrition*, pp. 6130–6137. Elsevier.)

The Endosperm

The starchy endosperm, excluding the aleurone layer, is composed of three types of cells: "peripheral," "prismatic," and "central." The peripheral cells are the last to be initiated during grain filling and they tend to be smaller than the other endosperm cells (60 μm in diameter and 20–60 μm radially). In addition, they have thicker cell walls (8 μm). Several rows of elongated prismatic cells are found inside of the peripheral cells. They extend inward to about the center of the cheeks and are ~150–200 μm in length. The central cells are more irregular in size and shape than are the other cells. They are located inside of central endosperm.

The central endosperm cells are the first to be formed and they have thin walls (2 μm). Cell-wall thickness also appears to vary among cultivars and between hard and soft wheat types. The differences between hard and soft wheat may be the result of selection: hard wheats (bread wheat) have been selected for high water absorption. The endosperm cell walls are composed of pentosans, other hemicelluloses, and β-glucans, but not cellulose. The pentosans in them absorb large amounts of water. The endosperm cells are packed with starch granules embedded in a protein matrix. Starch is the major component of wheat endosperm, comprising ~75% of milled endosperm.

Generally, the starch granules in wheat are classified into two size groups: large, lenticular (lens-shaped) A granules of up to 40 μm across the flattened side, and small, spherical B granules up to 10 μm in diameter. The B granules are formed later in the grain-filling process than are the A granules. The number ratio of small to large granules is ~3 : 7.

In bread wheats, the endosperm texture varies both in texture (hardness) and appearance (vitreousness). In general, high-protein hard grains are vitreous, whereas low-protein soft grains tend to be opaque. Some wheat grains are vitreous or translucent in appearance, while others are opaque, mealy, or floury. In vitreous kernels, with no air spaces, light is diffracted at the air–grain interface and it then travels through the grain without being diffracted again and again.

With vitreous kernels, the protein shrinks but remains intact, giving a denser kernel. As expected, the presence of air spaces within the endosperm makes the opaque grain less dense. The air spaces are apparently formed during the drying of the grain. If grain is harvested immature and freeze-dried, it becomes entirely opaque. This shows that the vitreous character results during intensive drying in the field. It is also well known that vitreous grain wetted and dried in the field, or for that matter in the laboratory, will lose its vitreousness. In durum wheat, which is much harder

than common hard bread wheat, a much larger number of starch granules are broken when the grain is fractured compared to bread wheat.

The Germ

The wheat germ is composed of two major parts, the embryonic axis (rudimentary root and shoot) and the scutellum, which functions as a storage organ (Figure 2). The scutellum is adjacent to the endosperm and contains the remaining two-thirds of the grain's thiamine content. The germ is quite rich in vitamin E (total tecopherol) and in B-vitamins. It contains many enzymes. The germ is a rich source of protein (25%), sugar (18%), oil (16% of the embryonic axis, and 32% of the scutellum are oil). The sugars are mainly sucrose and raffinose. On incineration, the germ gives a high level of ash (5%). The wheat germ comprises 2.5–3.5% of the kernel. Recovery of the germ during the milling process is an important step because of its value in the food and pharmaceutical industries.

Techniques for Studying Grain Ultrastructure

Many cereal scientists and technologists have successfully employed the three main branches of microscopy – light microscopy (LM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM) – to study the structure and composition of wheat and wheat-based products. Recently, X-ray techniques have been used to detect kernel cracks. The objective of the studies involves gaining fundamental information on the accumulation of cellular constituents in the developing wheat grain, as well as providing information that can improve the understanding of differences in processing ability and in the overall quality of wheat and wheat-based products.

Light Microscopy

The main stages in the preparation of samples for examination by LM are fixation, embedding, sectioning, and staining. The aims of fixation are to preserve samples from attack by enzymes or microorganisms, to render some constituents insoluble, and to strengthen the sample, thus improving its structural integrity during sectioning. The most commonly used fixative is aqueous, buffered glutaraldehyde, but specialized fixatives have been developed for specific applications (e.g., fixation of lipid-rich samples). Baked samples, which have been heat-fixed, may not require chemical fixation. Embedding, to provide additional support during sectioning, commonly involves aqueous gums for cryostat microtomy, synthetic resins, or special waxes. Resins are generally used where thinner sections are required and are cut using glass knives. Cryostat microtomy and sectioning of wax-embedded samples are carried out using steel knives. For examination, with transmitted bright-field illumination, stains are commonly used.

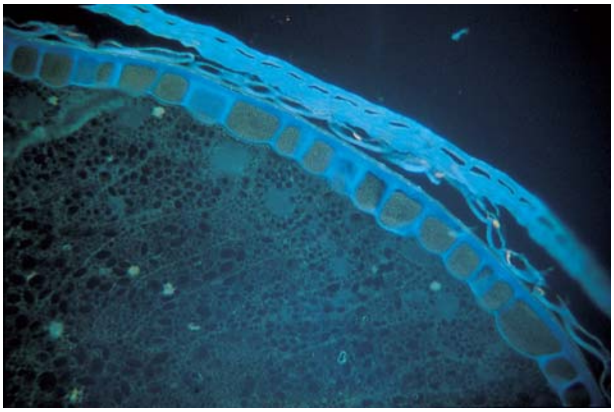

Figure 5 Fluorescence microscopy of the outer layers and outer endosperm of a section of wheat grain. The effect of auto-fluorescence provides contrast for the cell walls of the aleurone layer. (Courtesy of B Campbell.)

The ultrastructure of the wheat grain is illustrated in Figure 3. This micrograph was obtained by cutting a thin section from the grain, fixed with Spurrs medium. The section was stained in toluidine blue before viewing. The outer bran layers can be seen as distinct from the endosperm cells, further inside the grain. The crease is very obvious, extending well into the outer circle of the grain. The vascular bundle is seen at the innermost extent of the crease. Magnification by LM is generally less than is provided by electron microscopy, as can be seen by comparing the light micrograph of Figure 3 with the scanning electron micrograph of Figure 4.

Fluorescence microscopy has been widely used and may rely on auto-fluorescence or the application of fluorescent dyes, often coupled to specific antibodies or lectins. Other coupled antibody techniques have been developed whereby colored reaction products are produced. Figure 5 shows an example of the use of auto-fluorescence to highlight the outer layers of the endosperm, with special contrast being provided for the cell walls of the aleurone cells.

Polarized light can be used to study starch gelatinization or to provide detail of cell-wall structure. Native starch granules viewed under polarized light show a cross-shaped structure, known as the "Maltese cross" phenomenon (Figure 6). It is indicative of the crystalline internal structure of the granules in their native state. This feature is not seen after starch granules have gelatinized due to the effects of moist heat

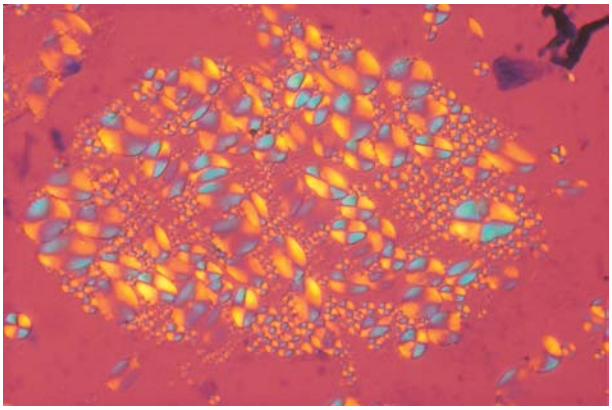

Figure 6 Starch granules viewed under polarized light, showing the "Maltese cross" effect on the granules. (Courtesy of R Moss.)

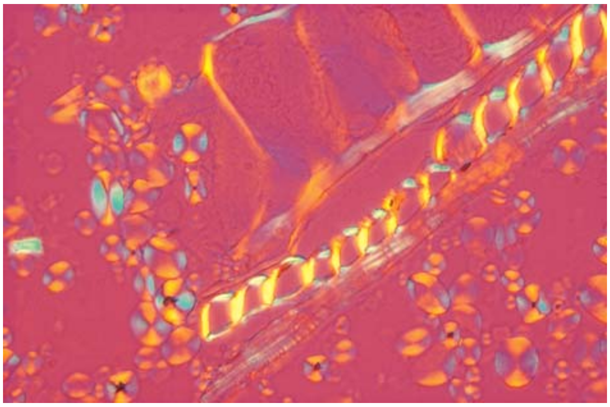

Figure 7 Bran layers of wheat viewed under polarized light, showing the effects of polarized light on bran fragments. Some starch granules are also visible. (Courtesy of R Moss.)

on their crystalline structure. This technique is thus a useful means of determining the status of starch granules, with respect to their crystalline state. Viewing under polarized light also produces distinctive pattern for bran particles, making them easier to detect their presence in white flour (Figure 7). One of the major changes that can take place during the cooking of baked products is the gelatinization of the starch granules. The extent to which this has occurred is easily followed using polarized light microscopy.

In Figure 7, light macro-photography has been used with a video camera to examine the wetting of wheat endosperm with water. The three frames of Figure 8 show parts of this sequence. Water, added to the section of endosperm, has started to form strands of gluten, which are seen streaming away from the otherwise dry section of endosperm.

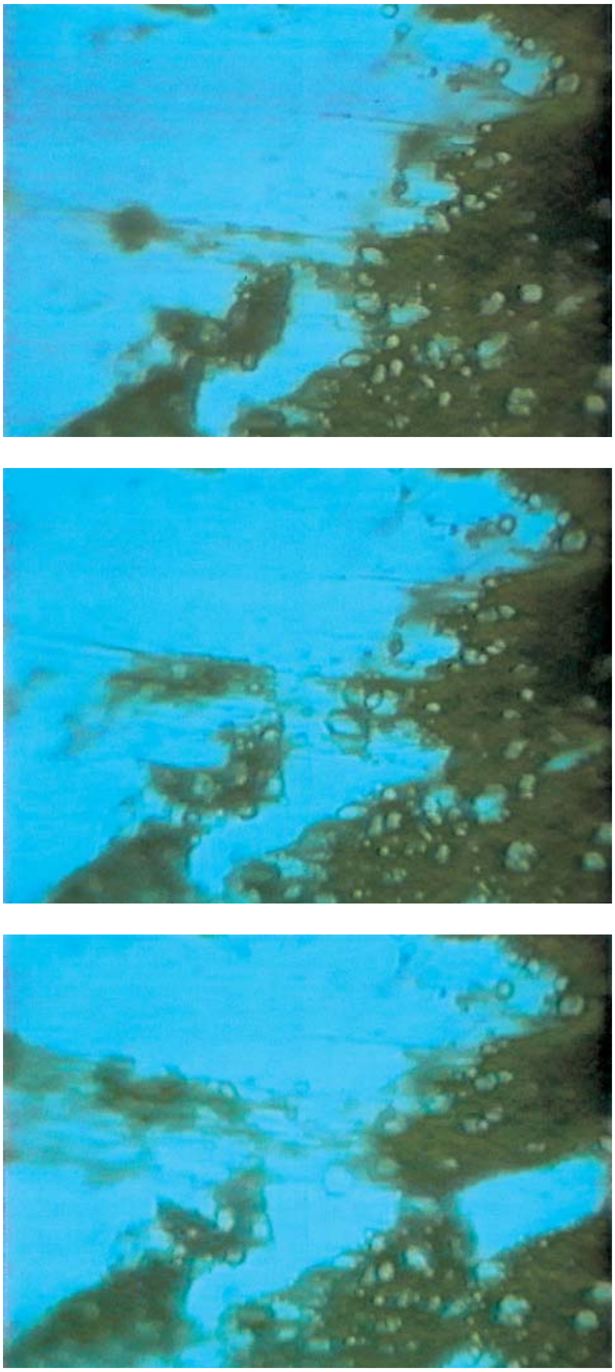

Figure 8 Successive frames from a video of wheat endosperm being wetted with water. Strands of gluten can be seen forming and streaming away from the dry endosperm mass at left. (Courtesy of J Bernardin.)

Scanning Electron Microscopy (SEM)

SEM has a greater depth of focus than LM and therefore it is not necessary to section samples prior to examination. Samples are normally coated with a thin layer of an electrically conducting material, usually gold, platinum, or carbon, prior to

examination. Samples of dry wheat (<12% moisture) or similar products only require air-drying over a desiccant prior to coating. Samples containing more moisture may be rapidly frozen prior to dehydration, using freeze-drying or critical-point drying. The development of cold stages in SEM has obviated the need for drying and this technique, together with freeze-etching, has been successfully used to examine cereal foods in which moisture is high, forming an integral part of the structure.

Endosperm hardness influences the manner in which grains fragment during milling, and this can also influence the yield of white flour. The efficiency with which floury endosperm is removed from overlying bran and the degree to which bran is powdered or otherwise damaged are both influenced by the manner in which grain fractures during milling. If fracturing occurs at the boundary between the endosperm cell wall and cell contents, the endosperm is efficiently removed from the bran, but the bran is fractured into small pieces. Figure 4 shows the cut surface of a wheat grain. Some signs of rupture between cells are visible.

When the endosperm is fractured intracellularly, bran clean up is poor, but large pieces of bran are produced. The manner in which the grain is fractured is determined by both the inherent hardness of wheat grain and its moisture content. Therefore, these two factors are carefully monitored by the flour miller. Grain of known hardness is sought for milling into specific types of flour, and grain is "conditioned" to appropriate moisture content prior to flour milling.

Transmission Electron Microscopy

Samples for TEM require fixation and thin sectioning. Initial fixation is usually with glutaraldehyde followed by fixation with osmium tetroxide. The fixed tissue blocks are rinsed, dehydrated, and embedded with a resin prior to sectioning. Heavy metal salts are used to stain the sections and enhance contrast; more recently, antibody staining has been developed whereby the antigenic sites are located at TEM level by the presence of colloidal gold particles, which are coupled to the antibodies.

Image Analysis and Other Techniques

During the 1990s, the value of all the above work was enhanced by high-tech methods, such as magnetic nuclear resonance, laser, and X-ray methods. More recently, the application of stereology techniques and automatic image analysis of grain have been used. Furthermore, user-safe X-ray techniques have proven to be highly suitable for visualization of mechanical damage of grain, especially inner cracks in kernels or insect infection (Figure 9). Mechanical damage occurs wherever grain is subjected to the destructive action of internal or external forces, causing internal cracks.

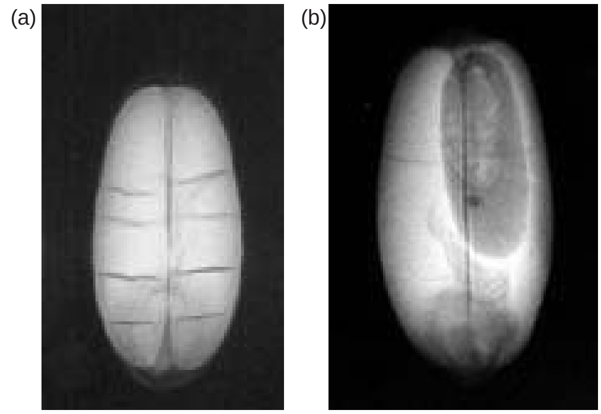

Figure 9 The X-ray images of wheat kernels: (a) kernel with inner cracks and (b) kernel with a weevil larva inside it.

The results of research carried out by using X-ray method showed significant differences in grain endosperm cracks between common wheat varieties. Natural wetting of dry grain (below 15% of moisture content) during rainfall when wheat is standing in the field is one of the reasons of its cracking. The susceptibility of wheat to mechanical damage is determined by genetic factors (e.g., grain hardness), environmental effects (climatic conditions during the pre-harvest period), and by the conditions of grain storage (especially excessive humidity). The combination of these properties determines the quality of grain material.

Radial cracks in the endosperm of a grain are shown in Figure 9, using X-ray microscopy to reveal these inner faults. X-ray detection makes it possible to identify the position of cracks and also to quantify cracks inside the kernel, and thus to evaluate the physical condition of the grain endosperm. Also shown in Figure 9 is the presence of a weevil larva that could not otherwise be detected. In this way, the stage of development of insect larvae living inside the kernel may be monitored, permitting the detection of insect infestation that is not visible by normal external examination.

The Ultrastructure of Wheat-Based Products

Flour Milling

The aim of the flour-milling process is to remove the endosperm from the crushed grain, separating it from the other anatomical parts of the grain, namely, the germ, bran, and scutellum. The particular aim is to obtain a maximum yield of white flour with the

minimum contamination of nonendosperm material. Fluted rollers are used to break open the grain and scrape the endosperm from the bran; smooth rollers are used to reduce the endosperm particles into flour. The moisture content of cleaned wheat is adjusted to between 15% and 17% prior to milling. This process ("conditioning") facilitates the separation of bran and endosperm and toughens the bran, thereby reducing the amount of ash in the flour.

Conditioning can be completed in ~6 h for soft wheat, but hard wheat may require 24 h or longer. X-ray microscopy has shown that added water moves rapidly through the bran layers, but may remain at the aleurone–endosperm interface for several hours. The rate of water penetration through the endosperm is dependent on protein content, initial moisture, and grain hardness. The air spaces that are present in the endosperm of soft wheat allow water to move more rapidly and hence the conditioning time is less than that required for hard wheat.

Of the morphological factors that can influence the yield of white flour, the shape of grain and the amount of endosperm within the grain are particularly important. Grain size has been shown to be significant; larger grains have a higher potential flour yield. Image analysis has been used to measure a large number of morphological parameters, and extraction has been shown to correlate with grain-length parameters.

In addition to the amount of endosperm contained in the grain, the efficiency with which bran and endosperm can be separated ("bran clean-up") is also a factor influencing flour yield. Because of differences in the structure of hard and soft grains, they must be milled differently. The cell structure of soft wheat is very weak and readily broken. In addition, the endosperm of soft wheat appears to adhere strongly to the bran. Durum wheat is used to produce semolina, a granular material analogous to the farina or flour middlings of the hard-wheat milling process. Granular products such as semolina and farina are used for pasta, baby foods, and specialty foods.

Endosperm hardness influences the manner in which grains fragment, and this can also influence flour yield. An important difference between hard and soft wheats is the boundaries of endosperm fragmentation. In hard wheat, it takes place mainly at the boundary between adjacent cells as the contents of the cells are more firmly bound together by the continuous matrix protein. Thus, hard wheat endosperm can be removed more efficiently from bran as the shear forces imparted by the fluted rollers are directed along the boundary between adjacent endosperm cells towards the bran (Figure 10).

When they reach the bran, some of the forces are deflected along the endosperm interface, facilitating separation of the endosperm from the bran. Of course, as the kernel is reduced to flour size, the hard wheat cell contents are also fractured. In soft wheat, the discontinuities in the protein matrix allow endosperm contents to break apart easily and cleavage takes place intercellularly. Thus the shear forces are dissipated within the endosperm are not redirected towards the bran. Figure 11 shows how

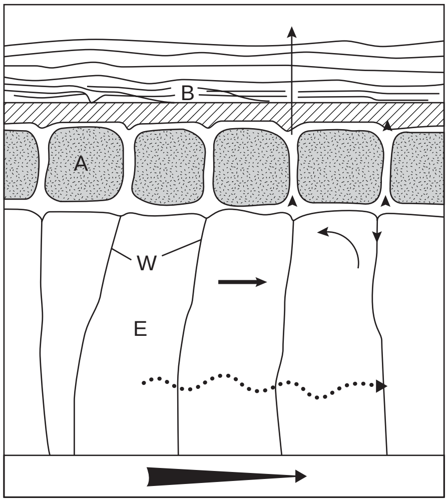

Figure 10 Diagrammatic representation of the forces acting on one endosperm cell of a wheat grain during milling. The large arrow at the bottom of the diagram indicates the direction of the shear force caused by the differential speed of the break rollers. In hard wheat, the contents of the cell behave as one unit, and hence the cell is cleanly torn from the overlying aleurone layer. In soft wheat, the shear force passes through the content of the cell, as indicated by the dotted arrow. B = bran layer. A = aleurone layer. W = endosperm cell wall. E = endosperm. Figure 12 Light micrographs of a cryostat section of an under-developed bread dough (left) and of a fully developed dough (right). The stain was Ponceau 2R. For the under-developed dough, the coarse gluten masses (M) that do not surround the majority of the starch granules (G), as they do, by contrast, for the developed dough which has become more interconnected and forms a continuous network (N). The bar is 60 μm long. (Reproduced with permission from Macrae R, Robinson RK, and Sadler MJ (eds.) (1993) Wheat: structure of wheat and wheat-based products. In: *Encyclopedia of Food Science, Food Technology and Nutrition*. London: Academic Press.)

the starch granules are released from a soft wheat, clean of adhering interstitial protein, which remains adhering to the starch granules from a hard wheat.

Microscopy can also be used to study the mode of action of different items of mill equipment and the effect of processing variables on flour quality. Starch damage is regulated by the amount of pressure applied by the smooth reduction rollers. The physically damaged granules absorb more water and are more susceptible to enzyme attack. A controlled level of starch damage is required for bread flours.

Dough Formation

When water is added to flour and energy is imparted to the dough by a mixer, the gliadin and glutenin proteins interact to form elastic, cohesive gluten. The tendency to form viscoelastic gluten can be seen even without mixing. Figure 8 shows a few frames from a video of allowing water to come in contact with a section cut from wheat endosperm, lying on a microscope slide. Immediately the gluten-forming proteins start to form fibrils that stream out from the endosperm section, carrying starch granules with them.

The mechanism and rate of gluten development depend on the level of water addition and rate of work input. In bread dough, the level of water addition (55–62%) is sufficient to cause the mixer initially to pull the gluten away from the starch granules and form coarse, poorly connected masses (Figure 12). As mixing proceeds, these masses are gradually stretched out and become more interconnected and eventually form a uniform, continuous, extensible network, which surrounds the majority of the starch granules in the dough. This gluten network gives dough a smooth external appearance, in turn leading to the production of well-risen bread of uniform crumb structure.

The level of water addition in noodle or pasta dough is considerably less (30–33% addition) than that in bread, and no protein pullback occurs during mixing. The function of mixing in these processes is to insure uniform distribution and hydration of ingredients. The continuous gluten matrix is formed by sheeting rollers in the case of noodles and by high-pressure extrusion in the case of pasta.

Conclusion

Thorough knowledge of the ultrastructure of the wheat grain, and of the products made from it, is essential to intelligent manipulation and optimization of wheat processing in all its forms. Much of this knowledge has already been translated into greater efficiencies, especially in milling and dough processing. Also needed is the integration of the knowledge of ultrastructure with chemistry and genetics. This overall picture will help in combining the efforts of technologists, chemists, and breeders, thereby to provide vertical integration from the original "design" of better varieties through to the final product and to the most important person in the business chain – the consumer.

Dough Rheology

B J Dobraszczyk, The University of Reading, Reading, UK

Introduction

Rheology is defined as the study of the flow and deformation of materials, conventionally applied to materials that flow within normal experimental timescales. Liquids and soft solids have viscosities in the range 0.1–10 000 Pa s (e.g., viscosity of wheat flour dough is ~1000–10 000 Pa s) (Table 1). Given enough time, most of the materials will flow, e.g., ice flows over decades in glaciers and rocks flow over millennia in the earth's crust, but these are generally regarded as brittle, elastic materials over normal experimental timescales (a few minutes) and are generally described by solid mechanics principles. The Deborah number (named after the biblical prophet Deborah, who said "The mountains flowed before the Lord") defines the flow of a material with respect to time. It is defined as the ratio of the time taken by a material to flow or relax and the time of observation. If the material takes a long time to flow, it will have a large Deborah number. The lower the Deborah number, the more fluid is the material. Dough relaxes very quickly, over a matter of a few minutes, and hence will have a low Deborah number.

Table 1 Typical shear viscosities of materials

Material	*Viscosity (Pa s)*
Bitumen	10^8
Polymer melts	10^4–10^5
Dough	10^3–10^4
Golden syrup	10^2
Molten chocolate	10^2
Set yogurt	3×10^1
Liquid honey	10^1
Tomato sauce	10^0
Glycerol	10^0

To measure rheological properties, deformation or strain is applied to a material in a controlled and quantifiable manner, and the resultant forces or stresses are measured to give an indication of the stiffness, modulus, or viscosity of the material. For materials which flow readily, shear stresses are commonly applied using standard viscometer geometries such as rotating parallel plates, cone and plate, and concentric cylinders. For complex fluids such as doughs, especially ones with long polymer molecules, the rheological properties measured in shear are very different from those measured in extension; therefore, extensional deformation is often applied by the imposition of a stretching flow.

Rheological measurements on dough have long been used to define its physical properties. The primary aims of these measurements are:

- to obtain a quantitative description of its mechanical properties;
- to characterize and predict its performance during processing and end use; and

- to obtain information related to its molecular structure and composition.

Rheology can tell us how a dough will behave under a given set of conditions and can be used to characterize and predict its performance during deformation, e.g., during mixing, sheeting, proving, and baking of dough. Rheological data are an important tool to process design, for example, of mixers and sheeters, or to predict the behavior of expanding bubbles within proving doughs, and to predict end-use quality ultimately. At the heart of this work lies the long-held belief within the baking industry that the rheological properties of dough, traditionally assessed by kneading and stretching the dough by hand, have a strong relationship with its eventual baking quality. This belief has been strengthened by centuries of empirical evidence, and there is no reason to doubt its validity. However, results from both conventional industrial methods of assessing dough rheology and modern fundamental rheological test methods have given disappointing relationships with baking quality. This is mainly because many of these tests are carried out inappropriately under deformation conditions far removed from those occurring during baking. This article will review rheological test methods applied to doughs and assess their usefulness for predicting end-use performance.

Historical Background

There has always been an intuitive feel for rheological testing, for example, in tactile and visual assessments of material properties such as hardness, stiffness, flexibility, and viscosity, and their relation to end-use quality characteristics. The quality of solid foods is often instinctively assessed by gently squeezing them, or liquid viscosity is assessed by gently rotating the liquid in its container, and these tests are often applied on the factory floor as a crude measure of quality. These intuitive assessments gradually became formalized into quantitative descriptions of material properties by scientists such as Newton (1687), Boyle (1662), Pascal (1663), Hooke (1678), Young (1807), and Cauchy (1827). Modern rheology as an independent discipline can be traced back to 1929, when The Society of Rheology was set up by a number of scientists working in complementary fields to secure an absolute standard for viscosity, and the name rheology was proposed by Bingham and Reiner to describe the study of flow and deformation of all forms of matter. Since then rheology has grown rapidly as a science and contributed to a number of applications such as colloids, suspensions and emulsions, polymer processing, extrusion, and polymer modeling. Recent developments in polymer rheology have established a quantitative link between the molecular size and structure of polymers and their rheology and end-use performance. Rheological measurements are increasingly being used as rapid, sensitive indicators of polymer molecular structure and predictors of end-use performance.

Rheological Test Methods

There are many test methods used to measure rheological properties, and the reader is referred to general reviews of rheology, rheological testing of foods, and cereal doughs given at the end of the article. It is common to categorize rheological techniques according to the type of strain imposed (e.g., compression, extension, shear, torsion, etc.) and the relative magnitude of the imposed deformation (e.g., small or large deformation) as well. The main techniques used for measuring cereal dough properties have traditionally been divided into descriptive empirical techniques and fundamental measurements.

Descriptive Rheological Measurements

Within the baking industry there is a long tradition of using descriptive empirical measurements of rheological properties, with instruments such as the penetrometer, texturometer, consistometer, amylograph, farinograph, mixograph, extensograph, alveograph, various flow viscometers, and fermentation recording devices (Table 2). Empirical tests are easy to perform and are often used in practical factory situations, providing data which are useful in evaluating performance during processing and for quality control. The instruments are often robust, capable of withstanding demanding factory environments, and do not require highly skilled or technically trained personnel. They have provided a great deal of information on the quality and performance of doughs such as consistency, hardness, texture, etc. However, these measurements do not fulfill the requirements of a fundamental rheological test since (1) the sample geometry is variable and not well defined and (2) the stress and strain states are uncontrolled, complex, and nonuniform. It is therefore impossible to define any rheological parameters such as stress, strain, strain rate, modulus, or viscosity. Therefore, these tests are purely descriptive and dependent on the type of instrument, size and geometry of the test sample, and the specific conditions under which the tests were performed. For example, empirical tests are used to characterize the behavior of bread doughs during processing, using instruments such as the extensograph, farinograph, and mixograph. Many of these

Table 2 Rheological methods used for cereal products

Methods	*Products*	*Property measured*
Empirical methods		
Mixers:	Dough	Mixing time/torque
Farinograph		Apparent viscosity

Lubricated compression		

are used as "single point" tests, where a single parameter is often arbitrarily selected from a whole range of data acquired during the test as, for example, in selecting the peak torque from a mixing trace and then using this to correlate with performance. This, however, neglects a large part of the recorded data, and is appropriate only to the set of conditions under which that test was performed, and which are generally not applicable to any other deformation conditions. Since dough experiences a wide range of conditions of stress states and strain rates during processing and baking, and the rheological properties of dough are dependent both on time and strain, there is often a discrepancy between such single-point-type tests and actual performance on the plant, where conditions of strain and strain rate may be poorly defined and very different to those in the laboratory test. It is impossible to compare results between different testing machines, or to extrapolate the results to other deformation conditions.

Doughs are viscoelastic and therefore their properties depend on how quickly the test is performed (the strain rate or frequency). This is important in many aspects of dough processing: if the dough is deformed quickly, for example, in mixing or sheeting, its rheological properties will be very different when measured at the typically slower rates of deformation found in conventional testing machines. Alternatively, performing a test under small deformation shear will give very different results to the large deformation extension conditions that dough experiences during sheeting or bubble walls experience during baking expansion. Performing a test under only one particular set of conditions of rate, temperature, and strain will almost certainly not be applicable to another set of deformation conditions: it is necessary to define the set of deformation conditions under which a dough operates in practice and then to perform the rheological test under these conditions.

Recording Dough Mixers

The farinograph and associated instruments such as the mixograph measure force or torque during mixing of doughs. These instruments are the most widely used physical dough testing machines found in

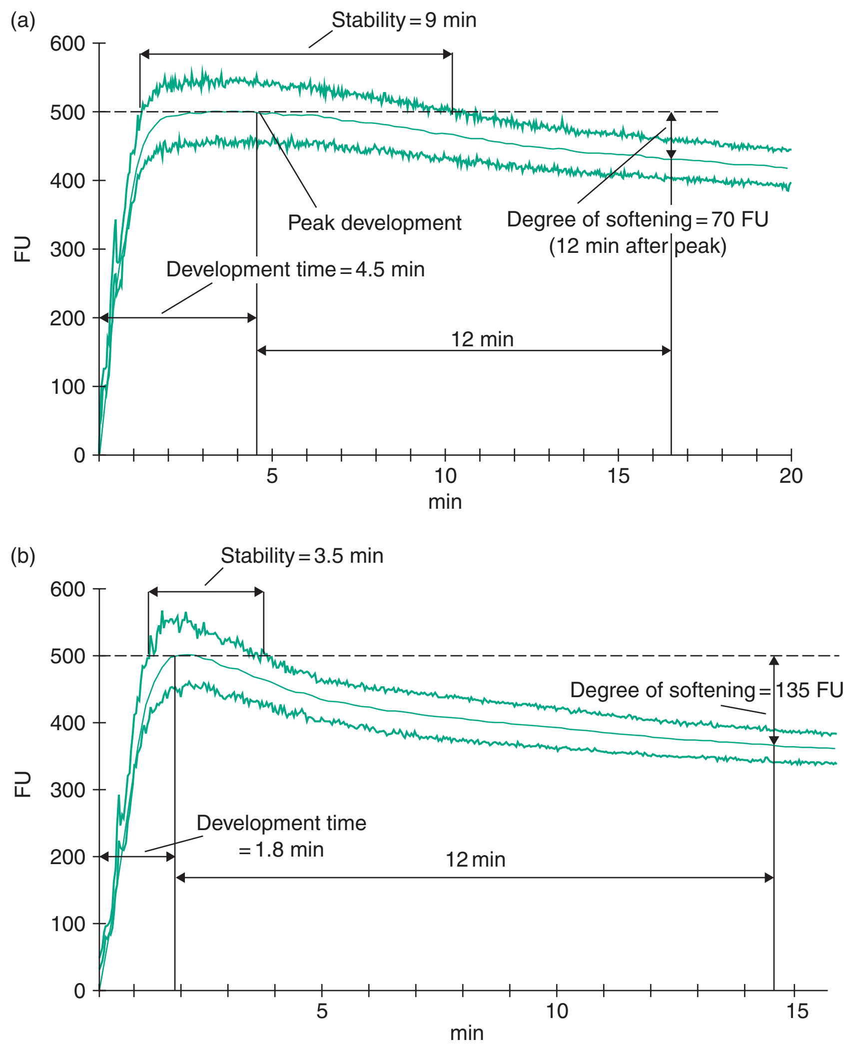

Figure 1 Analysis of farinograph mixing traces for a (a) strong flour and (b) weak flour showing commonly measured parameters. (Reproduced with permission from Brabender OHG, Duisburg, Germany.)

cereals' laboratories throughout the world. Their main uses are: (1) to predict the amount of water to add to flour to achieve a dough of fixed torque (consistency) during mixing (water absorption); (2) to measure the mixing characteristics of flour; and (3) to predict baking performance. The farinograph is a useful quality control tool for the baking and milling industries, and the mixograph provides an indication of the mixing requirements for relatively small amounts of flour (2–10 g), which is useful for wheat plant breeders in the early stages of selection of good quality traits in breeding programs.

The Brabender Farinograph, developed in the early 1930s, measures force or torque during gentle mixing of a dough at fixed speed using two counter-rotating z-blades mounted horizontally in a mixing bowl. Mixing torque is recorded as farinograph units (FUs) against time to give a mixing curve either on standard chart paper by means of a pen attached via a series of levers to a torque-recording device or directly onto a PC (Figure 1).

To calculate the water absorption, a fixed amount of flour (normally 300 g) is mixed with water. Water is added until a required maximum consistency is reached (usually 500 FU or 600 FU in the UK) at the center of the mixing curve. The amount of water added to achieve a required consistency is known as the water absorption, which can vary from 50% for a soft biscuit flour to almost 70% for standard UK bread-making flours at 600 FU consistency. Measurement of consistency and water absorption allows one to predict the processing behavior. If too much water is added to flour, dough with low consistency will be difficult to handle

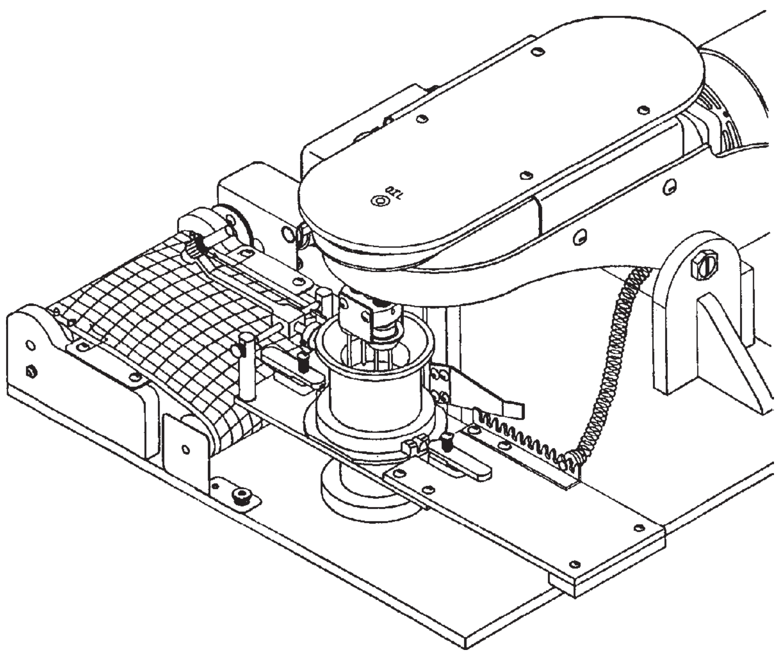

Figure 2 The mixograph. (Reproduced with permission from National Manufacturing TMCO Inc., Lincoln, Nebraska.)

and tend to be sticky. If too little water is added to flour, the dough will tend to be stiff and difficult to process, and unit costs will be higher.

The farinograph is also used to measure the mixing characteristics of dough. Flours of varying bread-making quality will produce different shapes of mixing curves. A poor bread-making flour produces a curve which rises rapidly to a maximum consistency (peak development), and then decreases rapidly on further mixing. A good bread-making flour takes longer to reach its maximum consistency and is much more stable, i.e., it shows little decrease in consistency (degree of softening) on further mixing (Figure 1). This is related to the stability of the gluten macromolecular proteins during mixing. Larger polymers, known to be related to good baking quality, are more difficult to break down than smaller ones, which is reflected in the shape and stability of the mixing curves from good and poor bread-making flours.

The mixograph, first described by Swanson and Working in 1933, is a similar recording mixer, which uses planetary rotating pins oriented vertically to mix the dough instead of blades (Figure 2). Torque during mixing is recorded either by a pen on chart paper or electronically via a torque transducer or, in more recent versions, by recording electrical output from the motor driving the pins, and mixing curves similar to those recorded by the farinograph are obtained (Figure 3). The detailed mixing curves appear quite different because of the nature of the mechanical connections between the dough mixer head and torque recording device and also because of the different nature of mixing action between the two. The mixograph imparts a higher rate of energy input into the dough and is therefore closer to the action of the high-energy input mixers used in mechanical dough development processing in modern bakeries. In general, the mixograph uses much smaller samples: the latest model requires only 2 g of flour, whereas older models require 10 or 35 g of flour. The use of the mixograph is largely limited to North America and Australia. Both the mixograph and farinograph have been used to predict dough processing properties and baking quality, based on the assessment of the mixing curves. The major problem with this is that interpretation of the curves is highly subjective, and is based as much as on the "feel" of the operator as on any objective assessment of the curve. Quantification of a complex mixing trace, for example, obtained from torque-recording mixers is difficult, and has not been tackled to any great degree.

The most widely used mixograph parameter to discriminate dough quality characteristics has been "time to maximum torque" (peak mixing time), mainly because it was easiest to determine before computerized analysis of the mixograph curve. However, many recent publications have shown that peak mixing time is a poor discriminator of baking quality as measured by loaf volume. A major problem is that arbitrary selection of a single parameter does not fully describe the complex mixing curve, and that a selection of several parameters from the mixograph

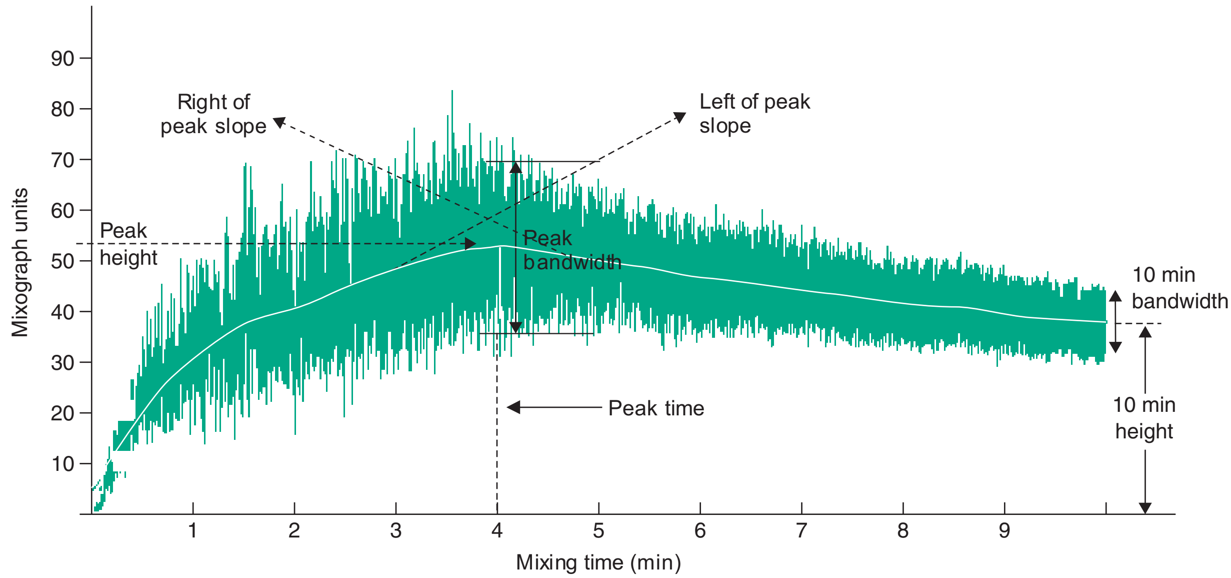

Figure 3 Typical mixograph curve showing commonly measured parameters.

curve using multivariate statistical analysis is much more successful in predicting baking volume.

Extensional Instruments

These instruments are designed to produce a large extensional or stretching deformation in the dough. Doughs often undergo large deformations in practice during processing, which often have a large extensional component. For example, extensional flows are important in mixing and sheeting of pastry and dough, converging and diverging of flow such as in extrusion and pumping, and expansion of bubbles in foams such as bread dough, cakes, and heat-extruded snacks. The Brabender Extensograph, Simon Research Extensometer, and the Chopin Alveograph are instruments used widely to obtain descriptive measurements of the extensional properties of dough.

The Brabender Extensograph measures the extensibility of the dough. A flour–salt–water dough is mixed to a fixed consistency in a farinograph, and it is shaped into a cylinder and allowed to relax for various periods of time at 30°C. The dough sample is clamped in a cradle and stretched by a hook passing through the center of the sample at constant speed. A curve of force against stretching distance is recorded by a pen on chart paper. The extensibility (E) and maximum resistance to extension (R_m) are derived from the force–distance curve (Figure 4). Good bread-making performance is generally associated with high resistance to extension and good extensibility with a large curve area (energy).

Analyzer are the other instruments which measure the extensibility of dough and gluten. In the extensometer, a ball of dough is impaled on the two halves of a split pin. One of the pins is driven upwards at a constant speed stretching the dough into an extended ring shape. Force and time are the recorded parameters. The Kieffer system is a recently developed instrument for the measurement of extensibility of doughs and glutens (Figure 5). This uses small samples of dough (10 g) or gluten (1–2 g), which is of particular value to wheat breeders in determining the processing qualities of new wheat strains at an early stage, when only limited grain quantities may be available. Small strips of material are produced in a grooved clamp arrangement, and then extended centrally by a hook passing through the sample. Force and distance up to failure are recorded on a PC.

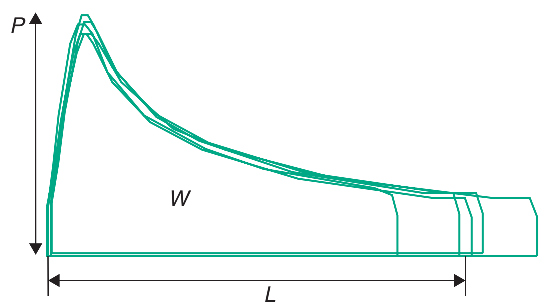

Figure 6 Alveograph curves for dough bubble inflation showing average inflation parameters. (Reproduced with permission from Tripette & Renaud, Villeneuve-la-Garenne, France.)

The Chopin Alveograph was developed during the 1920s as a test that would simulate the deformation conditions that a dough experiences during baking. A dough is prepared from flour, salt, and water using an integral mixer to a fixed water content (and therefore variable consistency) and then extruded from the mixer following standard procedures. The dough is shaped into flat disks and then given a fixed rest period of 20 min. Each disk is clamped at its circumference and inflated by air passing through a central hole in a base plate, resulting in an expanding bubble of dough. The bubble is inflated until rupture, and the inflation pressure is recorded versus time using a pen on chart paper (Figure 6). Commonly measured

Figure 7 *D/R* dough inflation system. (Reproduced with permission from Stable Micro Systems, Godalming, UK.)

parameters are: maximum pressure during inflation (P), which corresponds to the bubble attaining hemispherical dimensions, the maximum length or extensibility (L), which corresponds to the final volume of the bubble, and the area under the curve (W), which is proportional to the total energy used to inflate the bubble.

This instrument is widely used in France, Southern Europe, and South America to assess the bread-making potential of wheats. Good bread-making performance is usually indicated by high values of W and P. A recent development of the bubble inflation technique is the *D/R* dough inflation system by Stable Micro Systems, which measures fundamental rheological properties of the dough during inflation (stress, strain, viscosity, and strain hardening) (Figure 7).

Fundamental Rheological Tests

Rheological tests attempt to measure the forces required to produce controlled deformations, such as squashing (compression), bending, or pulling apart (tension), and to present them in such a way as to be independent of sample size, geometry, and mode

of testing. They measure a well-defined property, such as stress, strain, stiffness, or viscosity. A small test piece of the material is usually deformed in a controlled way, normally on a motor-driven machine, and the force is measured along with the distance moved or displacement of the object. These data are used to obtain a force–displacement curve. Normally for stiff materials we would divide the force and displacement by the "original" sample dimensions to obtain stress (force/cross-section area) and strain (displacement/original dimension), because the changes in sample dimensions are small and uniform; this allows us to remove the sample size as a variable. Many food materials are not stiff and undergo large deformations in practice, where the geometry often changes in a nonuniform and unpredictable manner, giving large and nonuniform stresses and strains along the sample. For example, dough thins out nonuniformly when stretched, in common with many polymers, giving rise to large stresses and strains not correctly calculated by the conventional method of dividing by original sample dimensions. It is then necessary to normalize by "actual" change in dimensions during deformation, in which case the sample dimensions should ideally be measured locally and independently by using contact extensometers or noncontact techniques such as laser, video, or photographic techniques. For materials which flow under normal measurement timescales (e.g., low Deborah number), stress is normally divided by strain rate (strain/time of strain application) to give viscosity.

Problems encountered with such fundamental tests are: (1) complex instrumentation which is expensive, time consuming, difficult to maintain in an industrial environment, and require high levels of technical skill, (2) often inappropriate deformation conditions, (3) difficulty in interpretation of results, and (4) slip and edge effects during testing.

The main types of fundamental rheological tests used in dough testing are: (1) dynamic oscillation, (2) creep and stress relaxation, (3) extensional measurements, and (4) flow viscometry (Table 2).

Dynamic oscillation measurements Adapted from techniques developed for measuring viscoelastic properties of polymer melts and concentrated solutions, this is one of the most popular and widely used fundamental rheological technique for measuring cereal doughs. These tests measure rheological properties such as elastic (G') and viscous (G'') moduli by the application of a small-amplitude sinusoidally oscillating (in time (t)) strain or stress and measuring the resulting response. For a viscoelastic material such as dough, the stress will be out of phase with the applied shear strain (γ_o), which gives a phase angle δ. For an elastic material the phase angle is zero: stress and strain are exactly in phase. This kind of test is normally carried out in a parallel plate geometry by rotating the upper plate with an oscillating angular velocity ω.

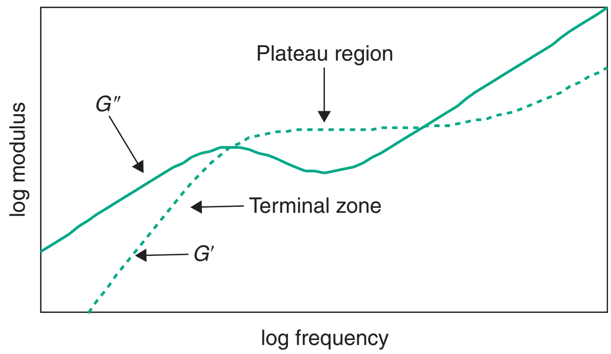

Figure 8 Effect of frequency on modulus for a polymer over a wide range of frequencies.

In general the oscillating stress (σ_t) can be represented as

$$\sigma_t = \gamma_o(G' \sin \omega t + G' \cos \omega t) \qquad [1]$$

The stress is expressed in terms of an elastic component called storage modulus G' and a viscous component called loss modulus G''.

Normally the values G' and G'' are measured over a range of frequencies. Figure 8 shows the main features of the viscous (G'') and elastic (G') behavior for a polymer over a very wide range of frequencies. The lowest frequency range (called the terminal zone) describes the longest relaxation motions of the polymer molecules, and is therefore related to the relaxation of the largest molecules within the polymer. The viscosity in this region (called zero-shear viscosity) is very sensitive to MW. Beyond a critical molecular weight (M_c), characteristic for each polymer, zero-shear viscosity (η_0) starts to increase rapidly with increasing MW, following a relationship $\eta_0 = K\mathrm{MW}^{3.4}$ for linear polymer melts, independent of polymer chemistry (where the constant K, depends on temperature and polymer concentration). Above this critical MW, the polymers start to entangle, giving rise to the observed rapid increase in viscosity with MW (Figure 9). If the polymers are branched, viscosity rises even more rapidly.

At intermediate frequencies, polymers show a well-defined plateau region where G' is approximately constant with frequency. For most polymers, the value of the plateau modulus is independent of MW. Figure 10 shows the effect of increasing MW on the dynamic shear modulus for a series of narrow MW linear polystyrene polymer melts. As the MW increases, a plateau in modulus begins to appear,

which increases in width as the MW increases further. The plateau represents the effect of entanglements, which at a certain polymer size effectively lock the polymer structure into a temporary three-dimensional (3D) network with a fixed modulus, the height of which is independent of MW. At some frequency the polymer network begins to disentangle, and the modulus starts to decrease rapidly into the terminal zone, where the polymer chains are free to move about and act as a viscous liquid. The larger the polymer, the longer it stays entangled, and therefore the wider the frequency range over which the plateau remains. Thus, it is the width of the plateau, or the point at which it descends into the terminal zone, which is defined by the MW of the polymer. Unfortunately, most rheological measurements on dough and gluten have been performed in the plateau region, which is the region most insensitive to differences in MW. If, as is generally accepted, large MW glutenin polymers are responsible for the variations in bread-making performance between different wheat varieties, it is to be expected that measurements of the plateau modulus will not be good indicators of baking performance.

Figure 11 shows the relationship between the wt.% fraction of increasing polymer MW size fractions extracted from gluten up to values $>10^8$ (measured by field-flow fractionation and light scattering), plateau storage modulus (G' at 1 Hz) of gluten, and the corresponding baking quality from a number of wheat varieties of varying baking performance. These show that neither plateau modulus nor baking volume is related to MW up to a size of about 5×10^8. This confirms the observation that plateau modulus is essentially independent of MW and also that it is not the size of the soluble glutenin polymers, but the insoluble polymer fraction that is mainly responsible for baking performance. This does not support the commonly held view that the MW of the glutenin polymers is related to their small deformation

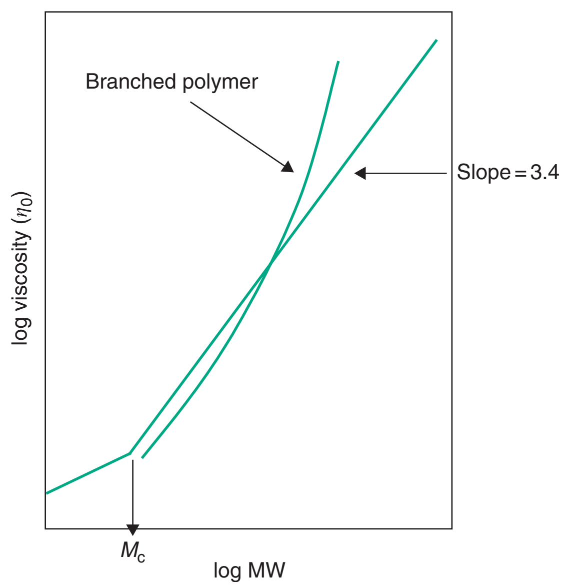

Figure 9 Effect of MW and branching on zero-shear viscosity for polymer melts.

shear rheology and to baking quality. Instead, it suggests that it is more likely to be the secondary molecular structure of the insoluble glutenin that is responsible for baking performance. Recent evidence suggests that these insoluble HMW polymers are entangled with a corresponding long relaxation time, they are branched and form extensive intermolecular secondary structures held together by hydrogen bonding, and differences in these structures are likely to be strongly related to extensional rheology and baking performance.

Such dynamic measurements have the advantage of a well-developed theoretical background, readily available instrumentation, and simultaneous measurement of elastic and viscous moduli, while the nondestructive nature of the test enables multiple measurements to be performed as temperature, strain, or frequency are varied. Disadvantages of the dynamic oscillation method are that the deformation conditions are often inappropriate to practical processing situations, because they are carried out at rates and conditions very different from those experienced by the dough during processing or baking expansion. For example, rates of expansion during proof and oven rise in bread doughs have been calculated between 5×10^{-3} and $5 \times 10^{-4}\,s^{-1}$, compared with measuring rates in rheological tests several orders of magnitude greater. Conventional oscillatory shear rheological tests usually operate in the linear region at small strains in the order of up to 1%, whereas strain in gas cell expansion during proof is known to be in the region of several hundred percent. Furthermore, most rheological tests are carried out in shear, whereas most large-strain deformations in dough (i.e., extrusion, sheeting, proof, and baking) are extensional in nature. From extensional studies on long-chain HMW polymer melts, it is known that entirely different rheological properties are obtained in shear than in tension, especially if the polymer chains are branched. For example, the elongational viscosity of low-density (branched-chain) polyethylene melts increases with both strain and strain rate (strain hardening), whereas the shear viscosity decreases with strain and strain rate (shear thinning), giving widely different values in final viscosities between elongation and shear (Figure 12). For doughs, shear and elongational viscosities at low strains are similar, with extensional viscosity slightly higher than shear viscosity, but at higher strains they

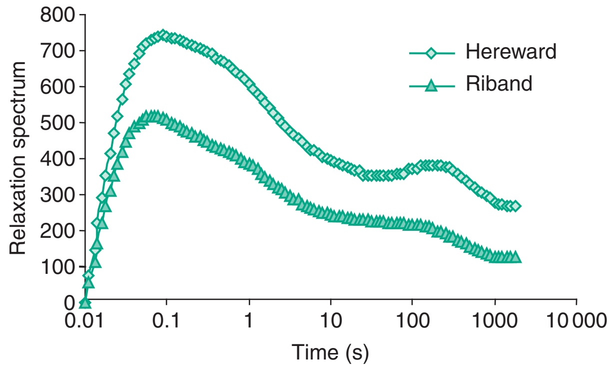

Figure 14 Typical relaxation behavior for two doughs (Hereward – typical UK bread-making wheat and Riband – typical UK biscuit wheat) showing two main relaxation processes: (1) a rapid relaxation at shorter times (~0.1 s), and (2) a slower relaxation at longer times between 100–1000 s.

diverge and the elongational viscosity rises steeply to give a value 2 orders of magnitude higher at failure (Figure 13). This increased strain hardening is attributed to entanglement of long-chain molecules during extensional flow, whereas in simple shear they remain coiled and can slip past each other, giving rise to observed shear thinning at higher strains. Therefore, it is considered that extensional strain hardening will be more sensitive to changes in the HMW glutenin polymers known to be responsible for baking quality.

Creep and relaxation measurements In stress relaxation measurements, deformation is held constant and the force response is measured, whereas in creep the stress is held constant and the deformation is measured. The stress of a material can be expressed in terms of its relaxation time:

$$\sigma_t = \sigma_o \exp(-t/\tau) \qquad [2]$$

where σ_t is the stress at any time, σ_o the stress at unit time, t the time, and τ the relaxation time. The relaxation time is related to the slope of a plot of log (stress or modulus) against time (Figure 14). Relaxation times are related to polymer MW and structure, with shorter relaxation times corresponding to small, rapidly relaxing molecules, and longer times corresponding to the relaxation of large polymer chains. Figure 14 shows that dough has two main relaxation processes: one with a rapid relaxation time up to 0.1 s, followed by a much longer time up to 1800 s. Relaxation results for doughs surveyed in the literature show that none of the curves show an exponential decay typical of a single relaxation time, but correspond to a decay typical of a number (spectrum) of relaxation times. This shows that a broad distribution of relaxation processes is responsible for this process within the dough, which is related to the wide MW distribution of gluten.

Many authors have shown that a slower relaxation time is associated with good baking quality, with relaxation time relatively independent of water content, mixing time, or temperature. Stress relaxation measurements on dough and gluten in shear showed that the relaxation behavior of dough could be described by two relaxation processes: a rapid relaxation process occurring over 0.1–10 s and a slower process occurring over 10–10 000 s. Measurements of large-deformation creep and shear stress relaxation properties were found to be useful in discriminating between different wheat varieties of varying quality. These measurements were also found to be closely associated with baking volume and strength of durum wheat varieties. At small strain amplitudes (0.1%) doughs with different baking quality showed no differences in relaxation behavior, but at a range of large strains (up to 29%) their creep and relaxation behavior was closely correlated with the baking behavior of dough. Doughs exhibited a characteristic bimodal distribution of relaxation times (Figure 14), with the second peak clearly discriminating between cultivars with varying strength and quality, which reflects the differences in the MW distribution (MWD) of glutenin polymers. The second relaxation peak is related to the entanglement properties of HMW glutenin polymers, and has been shown to be directly related to the insoluble fraction of the HMW glutenins. Relaxation properties of doughs relate well to the MWD of their gluten and particularly to entanglements of HMW glutenin polymers, and may be used as a rapid method of discriminating variations in MWD between cultivars that vary in baking quality.

Extensional techniques There are many types of extensional flow measurements, including simple uniaxial tension, fiber wind-up or spinning, converging flow, capillary extrusion, opposed jets, lubricated compression, and bubble inflation. Several methods have been used to measure the rheological properties of dough in extension: simple uniaxial extension, where dough is stretched in one direction; and biaxial extension, where the dough is stretched in two opposing directions, which can be achieved either by compression between lubricated surfaces or by bubble.

Uniaxial extension One of the most widely used test methods to measure materials properties is the uniaxial tensile test. A strip of material is clamped at both ends and pulled apart at a fixed rate in a suitable testing machine, and the force measured at the same time as the displacement of the object. These data are used to obtain a force–extension curve. Tensile tests may produce an approximately uniform extension of a sample provided necking does not occur. Normally the force and extension are divided by the original sample dimensions to obtain stress and strain, and allow removal of the sample geometry as a variable, but for doughs undergoing large extensional deformation the actual change in dimensions must be measured or calculated. The slope of the stress–strain curve then gives the elastic modulus or stiffness. Many test methods attempt to measure the uniaxial extensional properties of doughs, such as the Simon Research Extensometer, Brabender Extensograph, Stable Micro Systems Kieffer dough, and gluten extensibility rig, but none of these gives rheological data in fundamental units of stress and strain, because the sample geometry is not defined, dimensions change extensively and nonuniformly during testing, and it is therefore impossible to define any rheological parameters such as stress, strain, strain rate, modulus, or viscosity.

Studies on the fundamental uniaxial extensional rheological properties of doughs have been carried out by many workers. Some of the earliest attempts to characterize the fundamental rheological properties of dough were in a series of uniaxial extensional measurements by Schofield and Scott Blair in the 1930s, who stretched a cylinder of dough floated on a mercury bath and measured the elongation and force. Plastic and elastic components of deformation were resolved and viscosity and elastic modulus were calculated. They showed that the rheological behavior of dough is nonlinear with strain and strain rate, i.e., elastic modulus and viscosity vary with both rate and strain. The large-extension properties of doughs have been measured by extending a ring of dough suspended in a liquid of density equivalent to that of the dough between two hooks at constant deformation rates until rupture. The stress–strain curves showed considerable strain hardening (nonlinear increase of stiffness with increasing strain), and strain and stress at rupture were considerably lower for poor quality flours than for good quality flours.

Biaxial extension In biaxial extension, a sample is stretched at equal rates in two perpendicular directions in one plane, as in an expanding bubble. The most widely used methods for measuring biaxial extension properties of food materials are inflation techniques and compression between flat plates using lubricated surfaces, which produce purely extensional flow provided no friction occurs.

Inflation was first used as an empirical technique to measure wheat gluten and bread dough extensibility in the 1920s. This method was later developed to calculate rheological parameters, to measure the fracture and biaxial extensional rheological properties of wheat doughs and glutens during bubble inflation, and to assess the baking quality of wheat flour doughs (Figure 7). The major advantage of this test is that the deformation closely resembles practical conditions experienced by the cell walls around the expanding gas cells within the dough during proof and oven rise, i.e., large deformation biaxial extension. Extensional rheological properties can be measured at large strains up to failure and low strain rates, and the gripping problems normally associated with uniaxial tests can be minimized. Extensional rheological properties of wheat doughs have been measured using lubricated compression and bubble inflation. Differences in extensional strain hardening between varieties of different baking quality were found to relate to baking quality, with good bread-making varieties showing greater strain hardening and extensional viscosity.

Baking Quality and Rheology

The link between dough rheology and baking quality is long established, mainly due to empirical evidence from manual assessments such as kneading or stretching of dough by bakers after mixing. However, the results from conventional descriptive methods and fundamental rheological studies on doughs have often given disappointing correlations with baking quality, mainly because the deformation conditions in these tests are very different than those occurring during proof and baking.

Mixing is a critical operation in dough processing where, apart from the obvious function of mixing ingredients, the structure of the dough is formed. For example, in the production of batters, pastes, and doughs, the nature of the mixing action develops

the viscoelastic properties of gluten and also incorporates air, which has a major effect on their rheology and texture. There is an intimate relationship between mixing, aeration, and rheology: the design and operation of the mixer will develop texture, aeration, and rheology to different extents, and conversely the rheology of the food will affect the time and energy input required to achieve optimal development. This is seen in the great variety of mixers used in the food industry and the fact that certain mixers are required to produce a desired texture or rheology in a food. Studies on the rheology of mixing have focused on a number of areas: (1) the effects of mixer design and operation on the development of rheology and texture; (2) empirical measurement of rheology during mixing from mixer torque or power consumption; (3) effect of rheology on mixing patterns and performance; and (4) simulation and prediction of mixing flow deformation patterns as functions of mixer geometry and rheology.

Conventionally, most industrial practice has been to record torque traces obtained during mixing of doughs using instruments such as the Brabender Farinograph or the Mixograph. However, such measurements of motor power, torque, or energy do not give any direct information about the dough rheology. These measurements only give a qualitative description of the mixing deformation of the dough. Due to the complex deformation fields within the mixer and the constantly changing sample geometry, it is not possible to easily determine any rheological parameters. There are also many factors which influence the data being recorded from such mixers, such as motor and drive losses, frictional and surface effects between the dough and mixer, dough geometry effects, varying signal damping and data acquisition rates between different mixers, effects of aeration on rheology, and rheological relaxation effects. Most of the studies on doughs have been on the relationships between mixing, rheology, and baking performance, because of the rheological changes that occur in the gluten viscoelastic network during mixing and their importance for product quality. Despite the obvious importance of mixing in the development of rheology and texture in doughs, there is very little information in the literature on the rheological changes occurring during the different stages in the mixing process. Most work has either concentrated on the empirical measurement of mixer motor torque, voltage, or power consumption during mixing as a qualitative indication of changing rheology, or on the measurement of rheological changes at some time after mixing. Since dough is a viscoelastic material that shows rapid relaxation after deformation, which varies between different flours, such measurements are far from ideal and run the risk of giving misleading information. Nevertheless, much useful information has been obtained about the effect of mixing on gluten structure, rheology, and baking performance. Numerous studies have shown that rheological measurements after mixing parallel changes in mixer torque and power consumption, especially if rheological measurements are made under large, nonlinear deformation conditions closer to those experienced in the mixer. Recent studies have suggested that qualitative elongational rheological information during mixing can be derived directly from the torque/power consumption of a mixograph.

Extensive work on dough mixing has shown that mixing speed and energy (work input) must be above a certain value to develop the gluten network and to produce satisfactory bread making, and an optimum in work input or mixing time (peak development) has been related to optimum bread-making performance, which varies depending on mixer type, flour composition, and ingredients. If a dough is undermixed or mixed well beyond its peak development, then bread of inferior quality is produced. Kilborn and Tipples in a series of papers from 1972–77 investigated factors affecting dough development. Their results indicated that:

- for a given flour, there is a minimum mixing speed and energy input (the critical mixing speed or energy) below which development could not be achieved, resulting in a loaf of poor volume, color, and texture;
- the total energy input required for peak development differs between flour types; and
- both the total energy required and the critical mixing speed for a given flour differ between mixers with different mixing actions.

For example, mixing doughs by elongational flow in sheeting to achieve optimum development required only 10–15% of the energy normally used in conventional high-speed shear mixers, suggesting that much higher rates of work input can be achieved due to the enhanced strain hardening of doughs under elongational flow.

During mixing, there is a competition between the formation of intermolecular disulfide bonds (between adjacent HMW glutenin subunits) and cleavage of these bonds: the former promotes dough development and the latter gives rise to breakdown of the gluten polymer structure and opposes development. Many authors have shown that during mixing, large increases in solubility of the HMW glutenin polymer occur which are paralleled by decreases in MW. If doughs are mixed beyond their peak development, the gluten polymers are broken down into smaller

units, reducing the viscosity and elasticity of the dough. During resting, these smaller units are repolymerized by the reformation of disulfide bonds.

Proof and Baking

Fermentation (proof) is an important step in the bread-making process. During this process, the expansion of air bubbles previously incorporated during mixing provides the characteristic aerated structure of bread, which is central to its appeal. Although fermentation is clearly important in bread making, most rheological tests are performed on doughs without yeast and at room temperature and under inappropriate deformation conditions. Few studies have been made on the changing rheological properties during fermentation and baking. Direct rheological measurements have been made on yeasted bread doughs, cake batters, sour doughs, and cracker sponge and dough. Such measurements suffer from: (1) the problem of the evolving gas volume within the dough and (2) metabolites from fermentation, confounding the rheological data. The decrease in density as a result of increasing gas volume would be expected to have the effect of decreasing modulus and viscosity, but the compressibility of air counteracts this effect, especially at higher gas volumes and low densities where the moduli of the solid and gas phases converge, such as in cake batters, where shear modulus is directly related to the air content. Other approaches have been to measure the increase in height or volume of the fermenting dough using devices such as rheofermentometer or risograph, but these provide no direct information about the rheology of the material, since they do not measure force or deformation for corresponding change in unit dimensions.

Fundamental rheological studies on doughs related to baking have mostly been performed in small-deformation shear oscillations. Such dynamic rheological measurements on doughs have been investigated in many studies. Elastic (G') and viscous (G'') moduli for dough are measured over a range of frequencies. Elastic properties predominate over viscous properties, and the moduli are slightly frequency dependent, which is typical of a cross-linked polymer network. No convincing relationship has ever been established between dynamic rheological properties and baking performance. Various workers have found that flours of different baking quality have lower values of elastic (storage) modulus (G') for the higher baking quality flour. However, others have found that a higher value of G' for glutens and doughs relates to better baking performance (see Table 3). It has been shown earlier that these conflicting results arise, because most of these tests are carried out at rates and deformation conditions very different from those experienced by the dough during baking expansion, and also because dynamic rheological parameters in the plateau region are generally insensitive to differences in MW of polymers. However, these parameters are highly sensitive to changes in starch and protein concentration and diluents such as water, which are virtually never kept constant in rheological experiments on doughs. Most dynamic rheological tests on doughs and glutens have been carried out inappropriately over a relatively narrow frequency range in the plateau zone, because the value of the plateau modulus for polymers is known to be insensitive to the changes in MW and structure that are responsible for baking quality.

Table 3 Correlations between rheological properties and baking performance

Rheological parameter	*Baking parameter*	*Correlation*
Small deformation shear oscillation		
G' 1 Hz (dough)	Volume	0.15 ($n=48$)
G' slope		0.72
G' 10 Hz (wet gluten)	Volume	−0.85 ($n=27$)
	Form ratio (W/H)	0.65
G' 1 Hz (gluten)	Volume	N.S. ($n=20$)
	Form ratio (H/W)	0.69
Tan delta	(H/W)	−0.71
G' 1 Hz	Loaf height	−0.64 ($n=8$)
Tan delta		N.S.
G'	Volume	N.S. ($n=4$)
Large deformation		
Biaxial extensional	Volume	0.89 ($n=20$)
Strain hardening	Form ratio	0.80
Max. uniaxial	Loaf height	0.81
Extensional viscosity		
Biaxial strain hardening	Volume	0.92–0.97 ($n=6$)
Biaxial strain hardening	Volume	Good
Biaxial strain hardening	Volume	Good
Relaxation	Volume	Good
Creep		0.94 ($n=23$)
Relaxation	Quality	Good
Shear relaxation	Quality	Good
Shear viscosity		

During proof and baking the growth and stability of gas bubbles within the dough determines the expansion of the dough and therefore the ultimate volume and texture of the baked product. The limit of expansion of these bubbles is related directly to their stability, due to coalescence and the eventual loss of gas when the bubbles fail. The rheological properties of the expanding bubble walls will therefore be important in maintaining stability in the bubble wall and promote gas retention. The relevant rheological conditions around an expanding gas cell during proof and baking are biaxial extension, large strain, and low strain rate. Any rheological tests which seek

to relate to baking performance should therefore be performed under conditions similar to those of baking expansion. Methods such as bubble inflation and lubricated compression offer the most appropriate method for measuring rheological properties of doughs. The major advantage of these tests is that the deformation closely resembles practical conditions experienced by the cell walls around the expanding gas cells within the dough during proof and oven rise, i.e., large deformation biaxial extension can be carried out at the low strain rates and elevated temperatures relevant to baking.

Extensional rheology is sensitive to polymer chain branching and entanglement interactions between HMW polymers at large deformations. The theory is simple and relatively well developed, and it generally provides good correlations with the relevant large-deformation processing-quality parameters (Table 3). Disadvantages are that there is no single well-defined and accepted method for extensional measurement, with many different methods being used depending on the type and viscosity of the material being studied; the tests often use large amounts of material and they are destructive. The measurement of extensional flow is often difficult, because the deformation is large and nonuniform; it is therefore impossible to calculate strain directly from the machine displacement, requiring the direct measurement or calculation of changes in sample dimensions, often at high speeds.

The failure of gas cell walls in doughs has been shown to be directly related to the elongational strain-hardening properties of the dough measured under large deformation biaxial extension. Strain hardening is shown as an increase in the slope of the stress–Hencky strain curve with increasing extension, giving rise to the typical J-shaped stress–strain curve observed for highly extensible materials (Figure 15). Strain hardening in doughs is expected to arise mainly from stretching of polymer chains between points of entanglement in the larger glutenin molecules, which gives rise to the increasing stiffness observed at large strains. Under extensional flow, entangled polymers exhibit strain hardening which is enhanced for polymers with a broad MW distribution, particularly a bimodal distribution and branching. It is therefore expected that the broad bimodal MW distribution and branched structure typical of gluten will result in enhanced strain hardening and a bimodal distribution of relaxation times. Recent work has shown that bread doughs exhibit strain hardening under large extensional deformations, and that these extensional rheological properties are important in baking performance. Strain hardening allows the expanding gas cell walls to resist failure

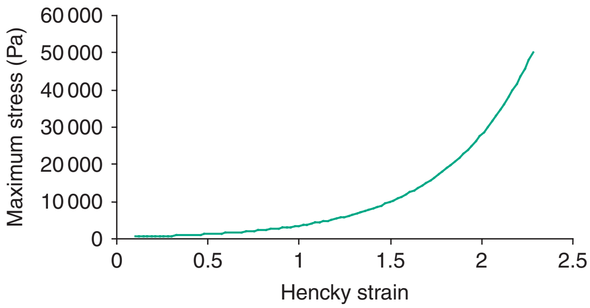

Figure 15 Typical J-shaped stress–Hencky strain curve in biaxial extension for a dough bubble. Bubble inflation using SMS dough inflation system, maximum stress, and Hencky strain calculated for bubble wall polar region.

by locally increasing resistance to extension as the bubble walls become thinner, and provides the bubble walls greater stability against early coalescence and better gas retention. It is therefore expected that doughs with good strain hardening characteristics should result in a finer crumb texture (e.g., smaller gas cells, thinner cell walls, and an even distribution of bubble sizes) and larger baked volume than doughs with poor strain hardening properties. It has been shown that good bread-making doughs have good strain-hardening properties and inflate to larger single bubble volume before rupture, whereas poor bread-making doughs inflate to lower volumes and have much lower strain hardening. Loaf volume for a number of commercial white flour doughs has been related directly to the failure strain and strain-hardening properties of single dough bubbles measured at elevated temperatures in biaxial extension. Strain hardening and failure strain of cell walls were both seen to decrease with temperature, with cell walls in good bread-making doughs remaining stable and retaining their strain hardening properties to higher temperatures (60°C), whilst the cell walls of poor bread-making doughs became unstable at lower temperatures (45–50°C) and had lower strain hardening. Figure 16 shows that bubble wall stability (indicated by a strain hardening value of 1) is increased to progressively higher temperatures with increasing baking volume, allowing the bubbles to resist coalescence and retain gas for much longer. Bubble wall instability in poorer bread-making varieties occurs at much lower temperatures, giving earlier bubble coalescence and release of gas, resulting in lower loaf volumes and poorer texture.

Summary

The use of rheological techniques for analyzing dough rheology has changed rapidly over the last few years.

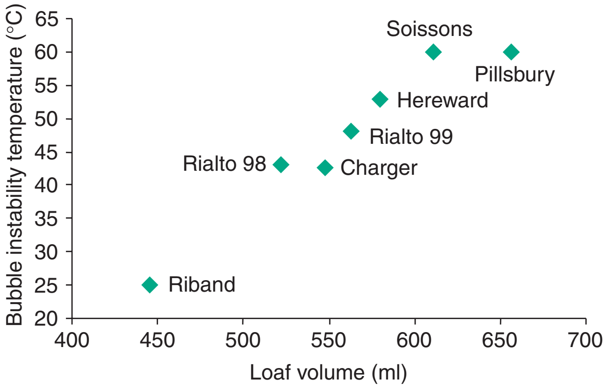

Figure 16 Temperature at which bubble wall instability occurs (as indicated by the temperature at which strain hardening drops below 1) for a number of wheat varieties vs. loaf volume.

The main aim of rheological testing of dough has been to assess gluten quality in relation to the main processes in bread making (mixing, sheeting, baking) and the final product quality. This is based on the long established practice of bakers assessing the dough quality after mixing by kneading or stretching the dough by hand and relating this to baking performance. Conventionally, such rheological tests have relied on descriptive empirical measurements of the deformation behavior of the dough during mixing, compression, or extension. However, severe limitations of these tests have been recognized because most of these tests are carried out under deformation conditions that are very different from those in the bread-making process.

New rheological tests have been developed which are based on modern polymer rheology principles, which relate the molecular size and structure of the gluten polymers to their rheology and end-use performance. Techniques such as large deformation stress relaxation, creep, and extensional strain hardening are sensitive to changes in interactions between polymers via entanglements, chain branches, and cross-linking which are seen to be the key mechanisms determining the rheology of the HMW gluten polymer network known to be responsible for baking quality.

Future Trends

- Small-scale rapid rheological tests will allow detection of desirable properties at earlier stages of selection of good quality traits in wheat breeding programs.
- Rapid advances in polymer molecular modeling, which attempts to relate changes in polymer structure to rheological properties, together with structural information from spectroscopic data, will soon enable prediction of the structure of the gluten polymer network.
- Development of scanning probe microscopy techniques (AFM, STM, etc.) for wet biological systems will allow direct imaging of the behavior of these polymers at a molecular level under deformation conditions similar to those of baking.

Grain Proteins and Flour Quality

F Bekes and M C Gianibelli, CSIRO Plant Industry, Canberra, ACT, Australia
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

Wheat is unique among the edible grains because only wheat flour has the protein complex called "gluten" that can be formed into a dough with the rheological properties required for the production of leavened bread. Gluten protein is the basis of man's attraction to wheat; it is the reason for the annual cultivation of enormous numbers ($\sim 10^{14}$) of wheat plants, because wheat gluten alone can sustain human desire for leavened-bread products. The rheological properties of gluten are needed not only for bread production, but also in the wider range of foods that can only be made from wheat, viz., noodles, pasta, pocket breads, pastries, cookies, and other products (Table 1). The unique properties of the gluten-producing storage proteins are formed in the white floury endosperm during grain development. Because of these unique dough-forming properties, wheat is the most important source of protein in the human diet.

Of the many species of the wheat genus (*Triticum*) (*see* **Taxonomic Classification of Grain Species**), there are only two major species that are grown around the world. The more popular of these two is *T. aestivum*, called "bread wheat." The other is durum wheat (*T. durum*), which is particularly suited to the production of pasta foods (*see* **Pasta**). Both bread and durum wheats are polyploid species containing three (AABBDD) and two (AABB) related genomes, respectively (*see* **Taxonomic Classification of Grain Species** and **Wheat**: Genetics). Many of the genes for protein synthesis are located on the group 1 and 6 chromosomes of these genomes, as illustrated in Figure 1 and Table 2.

Table 1 Quality attributes preferred in wheats for specific products

Product	*Protein content*	*Grain hardness*	*Dough strength*
Pan/sandwich breads	>13%	Hard	Strong
Flat/Arabic breads	11–13%	Hard	Medium
Steamed-Nthn China	11–13%	Hard	Medium/ strong
Steamed-Sthn China	10–12%	Soft/Medium	Medium
Alkaline noodles	11–13%	Hard	Medium
White/Udon noodles	10–12%	Medium/Soft	Medium
Instant noodles	11–12%	Medium	Medium
Biscuits/cookies/ grocery	8–10%	Very soft	Weak
Starch/gluten manufacture	>13%	Hard (soft preferred)	Strong

Adapted from Wrigley (1994) Developing better strategies to improve grain quality for wheat. *Australian Journal of Agricultural Research* 45: 1–17.

Historical Perspective

Although the term "protein," meaning primary substance, has been in use since about 1838, the terms "gluten," "gliadin," and "albumin" have even earlier origins. Gluten was one of the first few proteins to be studied, because it can be prepared so readily (by the water washing of dough) as a reasonably pure protein. This gluten-washing procedure has since become very big business internationally. This process has even been used as a rapid analytical method for determining the protein content of flour or wheatmeal samples (*see* **Cereals**: Protein Chemistry).

The importance of the proteins of flour for bread making has long been known. It is illustrated in a classic graph (Figure 2), published in 1948, relating variations in bread loaf volume to the protein content of different flour samples. The graph shows that baking quality increases with protein content for the same variety (thus illustrating the improving effect of protein quantity) and that for better varieties, increases in protein content produce greater increases (steeper slopes) in baking quality, showing the effect of protein

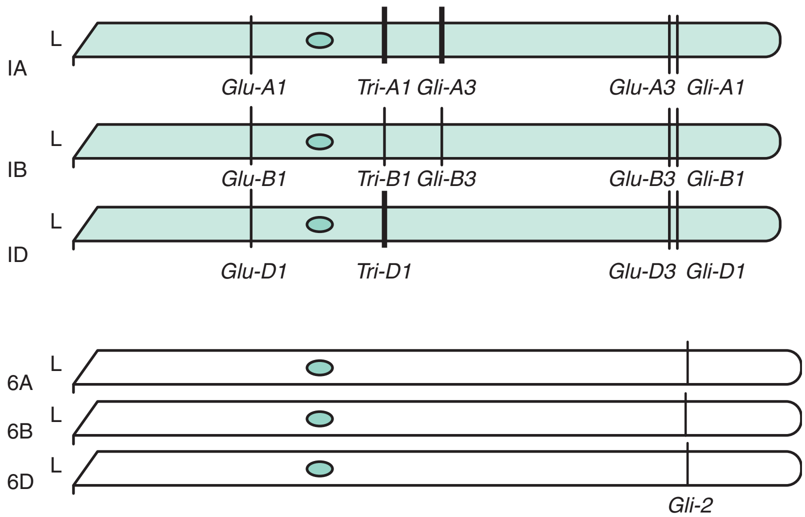

Figure 1 Locations of the genes for the synthesis of wheat-flour proteins. The long arm of each chromosome (indicated "L") extends to the left, containing only the *Glu-1* loci to the left of the centromere (indicated by a circle). See Table 2 for identities of most genes. Gene locations for the triticin proteins are indicated by the *Tri-1* loci. (Adapted from Gianibelli MC, Larroque OR, MacRitchie F, and Wrigley CW (2001) Biochemical, genetic and molecular characterization of wheat glutenin and its component subunits. *Cereal Chemistry* 78: 635–646.)

Table 2 Gluten–protein classification, based on chromosomal locations of the genes and on disulfide-bond formation

Class	*Gene locus*	*Chromosomal location of genes*	*Form of disulfide bonding*
ω-gliadins	*Gli-1*	Short arms of group 1 chromosomes	No SS bonds
α-, β-Gliadins	*Gli-2*	Short arms of group 6 chromosomes	Intrachain SS bonds
γ-Gliadins	*Gli-1*	Short arms of group 1 chromosomes	Intrachain SS bonds
LMW subunits of glutenin	*Glu-3*	Short arms of group 1 chromosomes	Interchain and intrachain SS bonds
HMW subunits of glutenin	*Glu-1*	Long arms of group 1 chromosomes	Interchain and intrachain SS bonds

quality (meaning "better loaf volume at the same protein content").

Because of the importance of gluten, much of the variation in quality between wheat samples can be explained in terms of the gluten component – its quantity and quality. Total protein content (Table 1) is generally taken as an indication of gluten quantity, although about one-fifth of the grain protein is non-gluten, including the range of enzymes and structural proteins.

Prepare Your Own Gluten

The historical importance of gluten in protein chemistry is due to the ease with which it can be prepared. It is a simple experiment to be performed at the kitchen sink. Mix some wheat flour with water, adding the water a little at a time, until a stiff dough is formed. Take the dough in the fingers and knead it under a gentle stream of water from the tap, placing a glass under the tap to catch the wash water. After the starch has washed out, to form a white sediment at the bottom of the glass, a ball of gluten is left between the fingers. It may feel like a piece of chewing gum, with stronger elastic properties than the original dough, due to the removal of the starch.

Wheat flour generally has ~9–13% protein, while the remainder is mainly starch, plus 1–2% lipid and some nonstarch polysaccharides. Flour, as milled, also contains ~14% moisture. About 20% of the protein in flour is water-soluble albumins and globulins; about 80% is gluten-forming proteins of which half is gliadin-type proteins and half is glutenin (Figure 3).

Why Is Protein Important?

The protein content and type is critical to the diversity of wheat-based foods listed in Table 1. For each of these groups of products, there is a recommended combination of protein content, grain hardness (largely determined by protein composition), and dough properties (a function of the gluten–protein composition). Other factors come into play, particularly good milling quality and suitable starch

properties (*see* **Starch:** Chemistry and **Wheat:** Dry Milling).

Of greatest importance is the gluten–protein component of the grain. On the one hand, it is important to the ongoing life of the wheat plant, because the gluten-forming proteins of the grain play their critical role in nature as a reserve of amino acids and nitrogen for the embryo upon germination. On the other hand, the gluten–protein component of the grain is imperative for the wheat industry because of its importance in determining processing quality.

Consideration of Table 1 indicates why wheat is segregated according to protein content after harvest and in international trade. More marketable parcels of grain can be obtained, appropriate to the processing needs of specific customers, if they suit relevant combinations of the attributes listed in Table 1. The other major factor used in segregation of wheat is variety; this factor takes into account genetic aspects of protein quality, especially grain hardness and dough properties. The genetic constitution of wheat is important because all quality traits result from the expression of genes and their interaction with the environment.

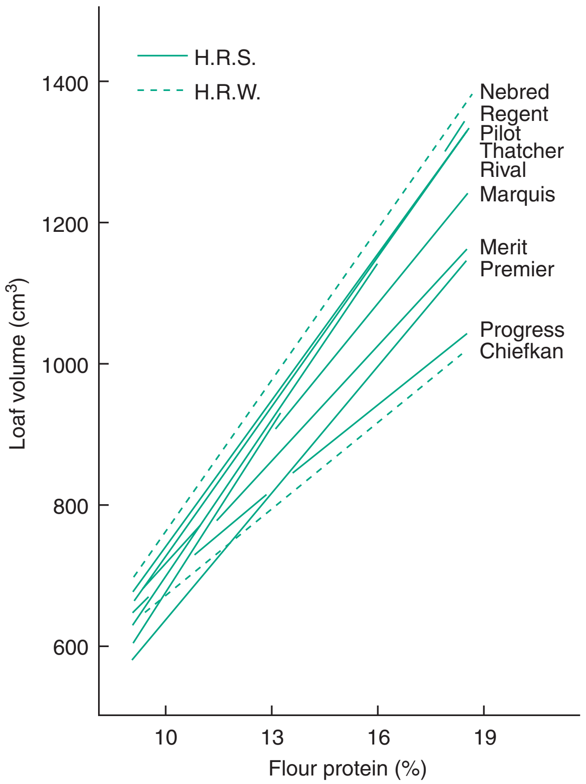

Figure 2 Demonstration of the distinction between protein quantity and protein quality. (Reproduced with permission from Finney KF and Barmore MA (1948) Loaf volume and protein content of hard winter and spring wheats. *Cereal Chemistry* 25: 291–312.)

Why Are Growth Conditions Important?

Because protein content and composition are modified by growth conditions, processing quality may not be entirely predictable, even if we know the variety and thus its genetic potential for processing into a specific type of product. The task of selecting wheat for optimum market value and processing quality is thus difficult. Nevertheless, we are learning much about what are significant aspects of protein composition and how these might be modified by growth conditions.

Growth environment is thus the "wild card" of uncertainty in using the combination of variety and protein content to select suitable wheat consignments.

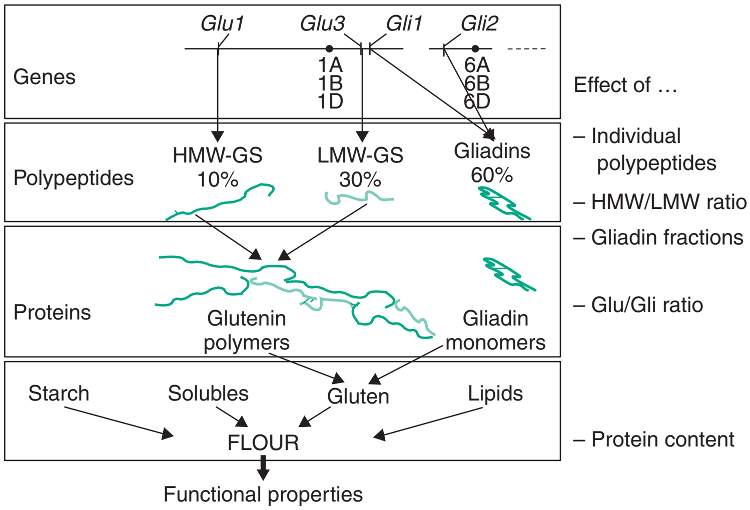

Figure 3 Relationships between the individual components of flour, especially gliadin and glutenin, the gluten-forming protein.

On occasions, for example, weaker dough properties may be obtained that are not those that would be expected from a particular protein-variety combination, leaving researchers with the job of working out the reason why.

Recent research has implicated interference from high temperatures (over 35°C) during the ripening of the grain. Evidence has been provided that these hot conditions may cause a redirection of protein synthesis, thereby changing the protein quality and thus the dough properties. Sulfur deficiency may be another environmental reason for variations in protein quality, particularly when nitrogen fertilizer is applied without sulfur. In fact, changes in dough properties have been observed for low-sulfur grain, accompanied by a decreased presence of the sulfur-rich proteins of gluten (Figure 4). Such occasional phenomena show that our tried and tested systems of selecting for grain quality still have some deficiencies to be rectified, possibly by screening harvest samples for protein quality, as well as for protein content.

Wheat Protein as Total Nitrogen Content

"Wheat protein" to many in the trade (the agronomist, the grain-elevator operator, the grain salesman, the miller) means no more than a single number, the result of analysis of total nitrogen content (*see* **Cereals:** Protein Chemistry). The digestion step in nitrogen analysis (lower half of Figure 4) generally involves: (1) the use of an oxidizing acid to transform all nitrogen-containing compounds (mainly protein) to ammonia for subsequent quantitation by titration in the Kjeldahl method, or (2) pyrolysis of nitrogen-containing compounds to nitrogen gas in the Dumas method.

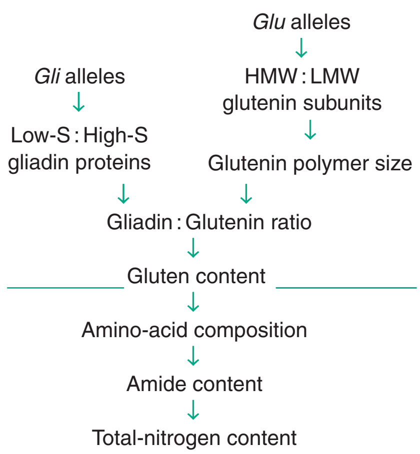

Figure 4 The degrees of formation (down to "gluten content") and disruption of gluten, illustrating the levels at which studies may be conducted on gluten–protein structure and function.

Currently, near infrared spectroscopy is routinely used to determine grain protein content, especially as a basis for segregation of wheat at the silo or elevator. This can be applied either to milled grain, as near infrared reflectance (NIR), or to whole grain, as near infrared transmission (NIT). This "instant" method involves scanning the sample in the infrared part of the spectrum, determining absorbance at certain wavelengths and computing protein content by comparison with a pretested set of calibration samples. The method is therefore comparative and it still relies on the basic reference methods for determining total nitrogen content.

It is feasible to use nitrogen content as a quantitative indicator of protein content since other nitrogen-containing compounds represent very minor components of the wheat grain. The factor 5.7 is generally used to convert the result of nitrogen analysis to protein content; this factor is much lower than the normal factor of 6.25 for other grains, reflecting the elevated level in gluten of nitrogen-rich amino acids, such as glutamine.

Determination of Protein Quality versus Quantity

The concept of characterizing protein by the protein content alone indicates loss of important information about protein composition. All such information is lost in direct (Kjeldahl, Dumas) analysis of total nitrogen content or in correlative methods (NIR, NIT) based on them. If amino-acid composition is known in addition to protein content, valuable additional information is provided about essential amino-acid levels, important in nutrition (Figure 4). However, even the analysis of amino-acid composition destroys information about the amino-acid sequences of proteins and these are essential to an ultimate understanding of protein quality.

Likewise, there is significant loss of information about protein–protein interactions as a result of extracting protein into dilute solution from flour or dough, especially if in doing so, we have broken disulfide bonds. Most methods of analyzing protein structure and composition involve extraction, but we need to remember that the resulting picture may still be different from what actually occurs in the water-poor medium of dough, where interactions with other groups of compounds (lipids and carbohydrates) are likely to assume greater importance.

In addition to information about protein content, the feed formulator needs to know about amino-acid

composition, particularly the content of essential amino acids. The general deficiency in the amino-acid lysine limits the nutritional value of wheat in feed for animals and in food for humans if protein is restricted in the diet. Knowledge about the content and sequence of amino acids in the many proteins of the wheat grain is fundamental to our understanding of their functional properties. This information has been accumulating over many years, but recent advances in molecular biology are providing this information at an increasing rate as nucleotide sequences are being provided, from which amino-acid sequences can be derived for the corresponding proteins.

The Diversity of Structure and Function of Wheat Proteins

Modern methods of protein fractionation have indicated that the protein of the wheat grain is made up of thousands of distinct protein species – these are needed to catalyze and regulate the synthetic processes of making a wheat grain, the host of enzymes needed in the germ, the scutellum and the endosperm to carry the process of life on into a new plant, and the reserve proteins stored away in the embryo and the endosperm to provide the building blocks for this ongoing process. This storage protein, gluten, is the plant's contribution to making another plant, even though for man, it is essential for bread making.

The structural requirements of a protein to meet these natural and industrial functions are similar in a key area, namely, solubility. Both functions require a protein of low aqueous solubility, first, so that these nutrients are not washed away from the imbibing seed, and second, for bread making so that the protein network of dough is not highly soluble. The nutritional need of the embryo is met by having storage proteins of low solubility, due to the high level of glutamine residues, together with the consequent efficient storage of nitrogen (two N atoms in the amino-acid glutamine).

The hydrolytic enzymes (particularly those with amylase and protease activities) that appear on germination are essential contributors to the ongoing plant-to-plant process, but they interfere with man's plans for bread making. Wheat breeders have sought means of reducing or delaying their production prior to the induction of the germination process, but there is the dilemma in this task of meeting the needs of both farmer and baker. Wheat grains that produce amylases and proteases before germination are described as pregerminated.

Diversity, Even for Storage of Proteins

Given the apparently simple requirements of a storage protein, it may thus have seemed reasonable at the dawn of cereal chemistry for cereal chemists to think of gluten as one protein, or even of gliadin and glutenin as single, homogeneous entities. We now know that even these storage proteins are many different proteins (polypeptides), each synthesized under the control of the appropriate gene (*see* **Proteomics**).

As the first products of gene expression, proteins are synthesized more faithfully, with less influence from environmental factors, than other groups of compounds. The DNA of genes in the nucleus is transcribed to produce messenger RNA, which in turn is the basis for translation to produce the newly synthesized polypeptide in the ribosome, with transfer RNA presenting the appropriate amino acids in the prescribed sequence as the polymer chain grows. The high degree of fidelity to genotype suits proteins well to the task of variety identification, the most common laboratory method for which, is the analysis of protein composition by gel electrophoresis or high-performance liquid chromatography (*see* **Variety Identification of Cereal Grains**).

The Gliadin Proteins

The gliadin proteins are used routinely for the identification of wheat varieties. Figure 5 shows the results of cathodic gel electrophoresis of gliadins proteins, which are readily extracted from flour with 6% urea solution or even with ethylene glycol (antifreeze). The water-soluble albumins and globulins are also extracted with the gliadins, but they migrate ahead of the gliadins under the electrophoresis conditions used, and they have been lost from the lower end of the gel.

The genes controlling the synthesis of the gliadin proteins are located on the short arms of chromosomes 1A, 1B, 1D, 6A, 6B, and 6D (Figures 1 and 3, and Table 2). At each of these six genetic loci, there is a group of genes responsible for a part of the spectrum of gliadin proteins. It is possible to separate out the gliadins associated with the each locus. This is demonstrated in Figure 6, with the respective "blocks" of gliadins drawn in separate columns beside the photograph of the original electrophoresis gel. The whole picture of all the gliadins in this case is obtained by superimposing all the drawn blocks of bands on top of one another.

The gliadin proteins contribute to the viscosity and extensibility of dough, due to their modest molecular size range (under 100 000 Da). The omega-gliadins are the largest in this molecular size range; they lack sulfur-containing amino acids (particularly

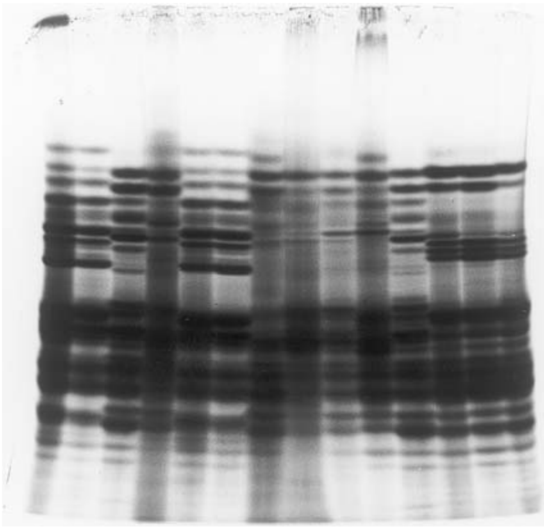

Figure 5 Gliadin proteins, fractionated by gel electrophoresis at pH 3 by the method used for routine variety identification in a precast polyacrylamide gel. Gliadin proteins, extracted into solution from flour samples, have been applied at the top of each vertical lane, and the respective protein zones have moved down the gel, under the electric field, until the current was stopped. The protein zones (horizontal bars) have been revealed in the gel with a stain. The eleven lanes on the left were all obtained from different samples of the Canadian variety Marquis, the remaining three lanes (at right) are samples of the variety Chinese Spring. The diversity of gliadin patterns for Marquis is unusual, presumably reflecting the age of this traditional variety, with such polymorphism arising from original heterogeneity, plus admixture and mis-labeling over many years.

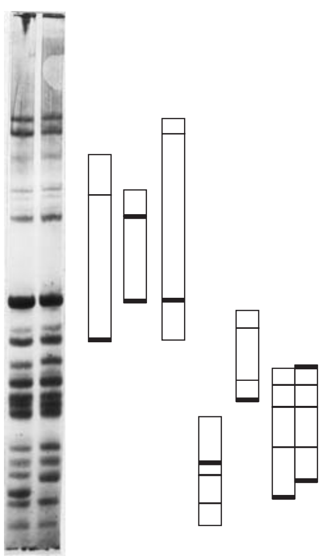

Figure 6 Gliadin proteins, fractionated by gel electrophoresis at pH 3 by a research method (photo of two lanes at left) from two biotypes of the Australian variety Suneca. The drawn block patterns to the right of the photo show the groups of gliadin proteins that are controlled by sets of genes on chromosomes (left to right) 1A, 1B, 1D, 6A, 6B, and 6D. The pair of blocks at the extreme right shows that the difference between the two biotypes arises with genes on chromosome 6D. (Illustration provided by Dr. E. Metakovsky.)

cysteine), so that there is no possibility of covalent bonding between the omega-gliadins via disulfide links (Figures 3 and 4, and Table 2). Although the other groups of gliadins (the α-, β-, and γ-gliadins) have sulfhydryl groups, the disulfide cross-links are mainly intra-chain, with no significant disulfide bonding between the gliadin polypeptides, so that they are monomeric (single polypeptide chains (Figure 3)).

The Glutenin Proteins – Polymers of Polypeptides

The lack of inter-chain disulfide cross-links for the gliadins distinguishes them from the glutenin polypeptides, which are extensively cross-linked to form polymers of glutenin subunits with molecular weights well over $\sim 10^5 - 10^7$ Da (Figure 3). Native glutenin, with disulfide bonds intact, contributes the resistance to the extension of dough, due to the sizes of these long polymers. They are depicted in Figure 7 as strings of glutenin polypeptides (appearing as coils) joined by disulfide bonds.

These large glutenin molecules are balanced by the smaller gliadin proteins in providing the appropriate molecular combination for dough quality and good baking properties. Thus, the ratio of glutenin to gliadin is a major determinant of protein quality. In addition, the size distribution of glutenin polymers is significant. Excessive dough strength and a long mixing time are associated with a high proportion of very large glutenin polymers. On the other hand, a lower size distribution provides a weaker dough, which is preferable for biscuit/cookie manufacture (Table 1).

The size distribution of the glutenin polymers appears to be partly determined by the composition of the glutenin subunits that form the polymeric structure. These subunit polypeptides are characterized by extracting them from flour in the presence of a reagent that breaks disulfide bonds, plus the detergent sodium dodecyl sulfate (SDS), followed by SDS gel electrophoresis (Figure 8). The high-molecular-weight (HMW) subunits appear at the top of the electrophoretic pattern (bracketed in Figure 8), whereas the low-molecular-weight (LMW) subunits appear further down the gel pattern, mixed with gliadin polypeptides.

The genes for the synthesis of the HMW subunits are located at the *Glu-1* loci on the long arms of the group 1 chromosomes (Figures 1 and 3, and Tables 2 and 3). These HMW subunits have been numbered 1, 2, 2*, 3, etc., down the SDS gel pattern. They often appear in pairs (e.g., 2 with 12, 5 with 10, 17 with 18) because their synthesis is controlled together in these pairs by

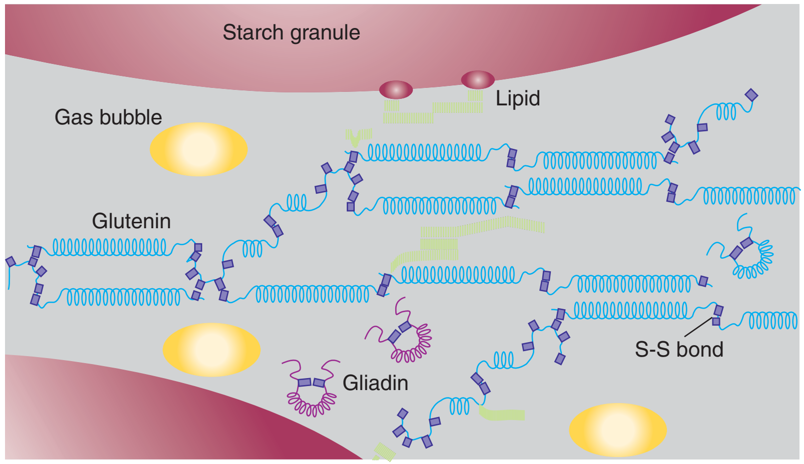

Figure 7 Diagrammatic representation of the molecules involved in dough formation (not to scale). The surfaces of two starch granules appear with some lipid coating. Gliadin molecules appear as single-chain molecules, contrasting with the polymers of glutenin, made up of subunits joined by disulfide bonds, either long or short coils (HMW or LMW subunits, respectively). Also present are gas bubbles and lipids between the starch granules. (Reproduced with permission from Wrigley CW (1996) Giant proteins with flour power. *Nature* 381: 738–739.)

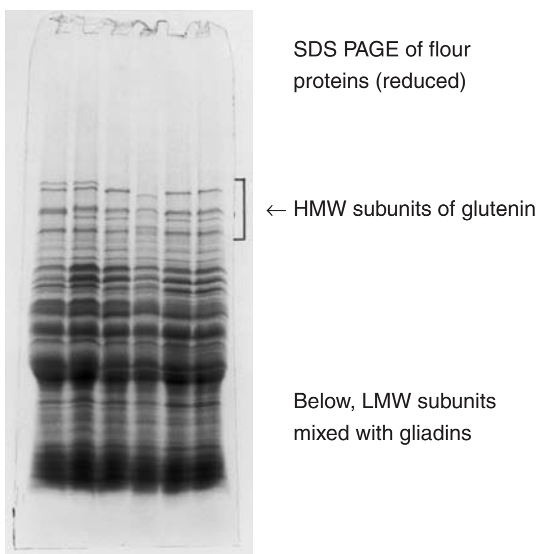

Figure 8 Polypeptides of flour, extracted from six varieties of wheat in the presence of the detergent sodium dodecyl sulfate (SDS) after breaking disulfide bonds, followed by SDS gel electrophoresis. The HMW subunits of glutenin are bracketed at the top of the pattern. (Adapted from Wrigley CW, Autran JC, and Bushuk W (1982) Identification of cereal varieties by gel electrophoresis of the grain proteins. *Advances in Cereal Science and Technology* 5: 211–259.)

genes at the *Glu-1* loci. For example, the *Glu-D1* locus may have either the *Glu-D1d* allele, corresponding to the subunit 5 + 10 combination, or the *Glu-D1a* allele, corresponding to subunits 2 + 12 (Table 3).

Table 3 The *Glu-1* scoring system to predict dough strength, based on the composition of HMW subunits of glutenin in a flour or grain sample

Score	*Glu-A1*		*Glu-B1*		*Glu-D1*	
	Allele	*Subunit*	*Allele*	*Subunit*	*Allele*	*Subunit*
4					*d*	5 + 10
3	*a*	1	*i*	17 + 18		
3	*b*	2*	*b*	7 + 8		
3			*f*	13 + 16		
2			*c*	7 + 9	*a*	2 + 12
2					*b*	3 + 12
1	*c*	Null	*a*	7	*c*	4 + 12
1			*d*	6 + 8		
1			*e*	20		

A score of 1, 2, 3, or 4 is allocated to each set of subunits for each locus (*Glu-A1*, *Glu-B1*, or *Glu-D1*), and these scores are summed to give a total score out of ten. A high score indicates a prediction of strong dough properties. This system is being used to help wheat breeders to select parents and progeny of suitable dough quality.

The HMW subunits of glutenin are more effective than the LMW subunits in contributing to the functional properties of glutenin, even though the LMW subunits are present at ~3 times the level of the HMW subunits. Even within each of these subclasses of subunits, some are more effective than others. In particular, within the HMW subunits, polypeptides such as those numbered 5 and 10 (the *d* allele, coded by the *Glu-D1* locus) are more effective than the allelic subunits 2 and 12 (the *a* allele; Table 3).

It has thus been possible to produce a *Glu-D1* scoring system (Table 3) by which to predict the dough

properties of a specific flour or grain sample, depending on the composition of the HMW subunits. This scoring system has proved valuable for breeders, who can use the system to predict quality by analyzing the protein composition of individual seeds, thus avoiding the much greater task of producing large grain quantities for milling and dough testing. Nevertheless, the prediction based on glutenin-subunit composition at best indicates genetic potential, not taking into account the effects of growth conditions on dough quality. The glutenin score is often used in the early stages of a breeding program, when there are thousands of lines to be screened, but small-scale milling and dough testing are used to determine protein quality in the later stages when the range of promising lines has been greatly reduced.

Future Prospects

Considerable research attention has been focused on the study of wheat-gluten proteins in recent decades, resulting in large numbers of research papers, review articles, and books on the general subject. A major impediment to research progress has been the difficulty in extracting the very large glutenin polymers into solution to permit more detailed study by current biochemical methods. In fact, the act of extraction into solution risks damaging the information that is being sought. Possibly, the future will provide novel methodology for the study of these unique proteins.

The application of the proteome approach (*see* **Proteomics**) offers a fresh new look to the problems of gluten functionality at the polypeptide level, opening the opportunity of identifying proteins that might not have been previously taken into account as wheat-quality modifiers during protein synthesis and processing in the immature endosperm. This approach offers better opportunities than before for the integration of DNA with protein studies, and thus for renewed approaches to the genetic improvement of wheat quality, including a better understanding of the complex interactions of gene expression with growth conditions.

WHOLE-GRAIN VERSUS REFINED PRODUCTS

D T Gordon, North Dakota State University, Fargo, ND, USA
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The nutritional guidelines developed by many countries recommend that the greatest intake of food types should be from the range of plant sources, especially grains. Within that broad category, the consumption of whole-grain foods is strongly recommended. These guidelines have been depicted in various pictorial forms, especially as a pyramid with the main ingredients of the diet shown as the base, with progressively less of other food groups shown as the smaller segments towards the apex of the pyramid (*see* **Nutrition**: Guidelines for Grain-Based Foods).

A recent re-evaluation of the nutrition pyramid of the USA recommends significant changes, namely, that the primary accent at the base should be for whole-grain foods, and that the consumption of refined-grain products should be moved towards the top of the pyramid. This accentuates the apparent dietary benefits of whole-grain products (e.g., whole-grain bread, brown rice) in preference to foods made from refined-grain products (e.g., white bread, white pasta, polished rice) (*see* **Nutrition**: Mineral Composition; Vitamin Composition).

Recently, such recommendations have been backed up by an explicit health claim authorized by the Food and Drug Administration (FDA) of the USA, namely "Diets rich in whole grains and other plant foods but low in total fat, saturated fat, and cholesterol, may reduce the risk of heart disease and cancers." Despite these clear indications of the health benefits of whole-grain foods, there has continued to be a degree of confusion in the public generally, as well as some controversy about the extent of the advantages of whole-grain foods. In addition, although there has been a modest swing from refined grain-based foods to those made from whole-grain ingredients, this has not been overwhelming in many countries. It is thus valuable to consider the range of factors that have been the basis of the whole-grain recommendations, to consider the extent that whole-grain advantages are still provided in other types of grain-based foods, and to examine these factors as they relate to the diversity of grain species (Table 1).

At its extremes, public comment has extended to the ridiculous with remarks such as "The nutritional value for a breakfast cereal made from refined grains is less than that of its cardboard packet." The confusion caused by such extremist comments has led to apathy for many people. Accordingly, government authorities and regulators have taken educational initiatives in many countries, with balanced campaigns to promote public awareness of the benefits of grain-based foods generally, and of whole-grain products in particular.

Historical Perspective

Whole-grain foods have long been basic to mankind's diet. Prehistorically, the cereal grains were an important component of the diet even when man, the "hunter–gatherer", included various types of grain in the daily gathering. Inevitably, these grains were consumed as the whole grain, after various forms of primitive processing, such as crushing, soaking, boiling, or baking (*see* **Cereals**: Overview). Then followed the development of technology of sieving to remove the coarse outer layers, to produce a flour of fine uniform particle size, which was deemed to be of better quality. This refined product was thus assumed to be better, perhaps because of the extra work involved in its production, and that its consumption conferred some prestige, suiting it to the upper classes. This sociological prejudice against whole-grain foods has continued right through to the present day, so that there is some disdain for foods made from whole-grain meal.

In contrast to these sociological considerations, there are classical stories of nutritional deficiencies

Table 1 The common cereal grains, common forms of processing, and the concepts of "whole-grain" and "refined" products

Cereal species	*Grain, as harvested*	*Initial processing*	*Further processing*	*Final product as usually consumed*
Maize	Grain on the cob, with outer bracts	Remove bracts and grain from cob	Wet or dry milling to isolate endosperm	Refined flour, as crushed endosperm
Sweet corn	Grain on the cob, with outer bracts	Remove bracts	Consume "as is" after boiling	Whole grain on the cob
Popcorn	Grain on the cob, with outer bracts	Remove bracts and grain from cob	Consume "as is" after heating	Popped whole grains
Rice	Grain with hulls	Remove hulls	Remove germ and bran layers	Refined grain, as whole endosperm
Wheat, rye, triticale	Naked grain	Dry milling to isolate endosperm	Baking of refined flour (endosperm)	Baked and extruded foods
Malting barley	Grain with lemma and palea	Submit to malting, "as is"	Brewing	Beer
Food barley	Grain with lemma and palea	Remove lemma and palea	Pearl off bran layer, leaving endosperm	Soup, from boiling whole endosperm
Oats	Grain with lemma and palea	Remove lemma and palea, leaving groat	Heat treatment of whole grain	Porridge, from whole grain

associated with the consumption of foods that are solely based on refined grains. These include nutritional problems associated with the consumption of milled rice versus brown rice containing the bran layer (Table 1) (*see* **Nutrition**: Beriberi, A Deficiency Related to Grains).

On the other hand, during the past century, attempts have been made to compensate for the loss of vital nutrients in refined products by adding back purified preparations of specific nutrients, such as vitamins and minerals in a process known as "fortification" (*see* **Fortification of Grain-Based Foods**). This process has been successful to the extent that it has probably enhanced the nutritional status of communities for whom fortified foods have been available, but it appears to be an expensive and inefficient means of enhancing public nutrition when the same advantages and more could be provided merely by avoiding the refinement process in the first place.

International Health Claims for Whole-Grain Foods

Quality cereal-food products start with appropriate selection for these qualities in plant breeding, and continue via appropriate farm management, harvesting and processing. However, acceptance at the consumer level is essential to the advancement of public health. Appropriate attitudes must be present in the mind of the consumer, encouraged by public knowledge about the components in cereals and improved food-processing techniques. The ultimate gain is achieved by providing quality grain for consumer food products. However, consumer acceptance is also based on quality taste, so there is a vital interplay between hedonic acceptance and "what is supposed to be good for you."

Education in health information is thus essential to motivate greater acceptance of nutritionally suitable foods in general, and of whole-grain foods in particular. In general, whole grains are promoted and perceived as being healthy compared to nonwhole-grain foods. Although nutrition information (nutrient content claims) is important for promotion of increased grain consumption, increased consumer interest lies in health concerns.

Health Claims in the USA

Consumers are interested in health claims and health messages. Information about foods and health is best received when the message is kept simple. Consumers receive health claims and messages as a positive input, while information about disease prevention and death statistics are perceived more negatively. In the USA, the health claim, with specific wording, must be displayed on a processed-food package. This is defined by FDA guidelines in the USA. For most health claims, lengthy scientific and clinical information is required. A common health message that may appear in bold letters on the front panel of cereal or food containers is "Helps lower bad cholesterol while maintaining good cholesterol." This wording may be best interpreted as making a health claim friendlier to consumers. Health claims are based on science, and science will continue to expand the use of health information about grains to benefit the consumer, the grain and food industries, and agriculture.

Although Sweden approved its first health claim recently, health claims have been unique to the United States. There are 14 FDA-approved health claims in the USA. Twelve of these claims are based on

a standard of scientific validity, which consists of two parts:

- that the totality of evidence supports the substance-disease relationship, and
- that there is significant scientific agreement among qualified experts that the relationship is valid.

The necessary scientific information to petition for a health claim is well-described by the FDA. This reference is highly recommended for anyone interested in understanding the various types and designs of research experiments necessary to draft and receive an approved health claim. Not all studies submitted in a health claim petition may statistically or adequately support the substance-disease relationship, but it is the totality of evidence that is considered. For the FDA-approved oat-bran health claim, 37 of 41 submitted clinical trails were accepted by the FDA. Seventeen of these studies demonstrated a cholesterol-lowering effect by oat/oat bran, four were inadequate in duration, five were equivocal, and 11 showed no effect.

Statement by US National Academy of Science

Two of the 14 FDA-approved health claims are based on the existence of an authoritative statement by an appropriate scientific agency of the United States. These two claims do not need the specific depth of scientific data required of the other 12 claims. These two authoritative statement-based health claims are for potassium and whole grains. Specifically, the whole-grain claim was based on the authoritative statement that appeared in a US National Academy of Science (NAS) Report, entitled "Diet and Health: Implications for Reducing Chronic Disease Risk (1989)."

The statement appearing in the NAS report reads: "Diets high in plants foods (i.e., fruits, vegetables, legumes, and whole-grain cereal) are associated with a lower occurrence of coronary heart disease and cancers of the lung, colon, esophagus, and stomach." Although this authoritative statement pertains to all plant foods, the petition and authorized health claim is specific only for whole-grain foods. At issue, and the purpose of this article, is the question of the inclusion of all grains in this claim. To be more specific, the current whole-grain foods health claim appears most applicable for whole wheat. If the whole-grain foods claim could be strengthened to include all grains, consumer awareness would be heightened and consumption of a greater variety of grains could be achieved. This issue is based on the belief that a greater variety of grains in the diet is more beneficial than a single-grain diet.

Every sector would have greater opportunities for gain if consumers knew more about the health benefits of all grains. The inclusion of all cereals or grains under one claim might induce food manufacturers to investigate and develop new whole-grain foods. Consumers still want foods which taste good and many grains may not acquire consumer acceptance because of undesirable taste characteristics. Some grains have only regional importance and significance in consumption. The whole-grain claim should be amended to allow for a wider variety of grain-based food products and those having a mixture of whole grains.

The Diversity of Grain Morphology

The cereal grains that are common in our diet are listed in Table 1, together with indications of how their diverse morphologies relate to the concept of "whole grain" and "refined" in our diet. There is considerable diversity in the structure and morphology of the many grains. This is evident even within the cereal grains that are commonly consumed (Table 1). For these reasons, the two key terms "whole grain" and "refined" are not easily defined. For cereal grains, however, "refined" can generally be regarded as material that consists mainly of the endosperm, with the outer layers of bran and glumes removed. Explanations of these aspects of grain morphology are provided in other articles, particularly **Cereals**: Overview. **Grain, Morphology of Internal Structure**; **Grain and Plants, Morphology** and **Oilseeds, Overview.**

Table 1 summarizes the processing steps for the various cereals, leading to the form in which each is normally consumed. These considerations provide the implications for possible loss of nonendosperm materials, e.g., loss of bran layers for milled rice and even the value of the outer husks of barley for filtration in the brewing process (*see* **Barley**: Milling and Processing; Malting). The summary in Table 1 is confined to the most common uses of these grains, omitting less usual uses and also omitting the uncommon types of these grains, such as the existence of hull-less genotypes in some cases, such as hull-less barley, which threshes free of the lemma and palea glumes like wheat.

Compositional Differences between the Grain Components

The basis of health claims for whole grains relates to the distinctive compositional differences between the outer layers of the grains and the endosperm, which is the inner floury tissue that constitutes the anatomical

"refined" product. Table 2 lists the fiber contents of a limited range of cereal grains. Details of the full range of nutritionally significant components are listed for a wide range of foods and raw materials in **Appendix**: Grain Composition Tables. It thus provides a ready means of comparing compositional details for whole and refined forms of the full range of grain species and for a diversity of food products made from them. It must be realized, however, that these values are indicative, and that the actual composition of a specific food may vary above or below these figures depending on the genotype (variety), growth environment, and processing conditions.

Examination of these tables indicates that there are considerable differences in various nutrients depending on whether foods are made from whole or refined materials, especially in nutritionally important components such as fiber, vitamins, and minerals. Examples of these contrasts are provided for wheat and rice in Table 3. The higher content of protein and fat in the whole-grain materials (whole-meal wheat and brown rice) especially reflect the presence of the germ (embryo) in the whole-grain materials, which are also richer in most of the vitamins and minerals. Nevertheless, despite these differences, it must be appreciated that there are very good levels of all these nutrients in the white wheat flour and in the white rice. Information on the significance of these many nutrients is provided in **Nutrition**: Effects of Food Processing; Mineral Composition; Vitamin Composition. **Wheat**: Ultrastructure of the Grain, Flour and Dough. The values given in Tables 2 and 3 are indicative, but actual values for a specific sample are likely to differ from these values, due to variations in growth conditions and genetic differences between varieties. For example, different sources of information have been used for the values for rice fiber in Tables 2 and 3 but the differences between brown and white rice are evident in either case.

Table 2 The dietary fiber content of cereal grains

Cereal species	*Form consumed*	*Dietary fiber content (g/100 g)*
Maize	Whole yellow corn	11.0
Rice	White, milled	1.3
Rice	Brown	3.5
Wheat	Whole grain	12.2
Rye	Whole grain	11.7
Triticale	Whole grain	14.6
Barley	Whole grain	10.3
Oats	Whole grain (groats)	9.5
Sorghum	Whole grain (25 pearled)	7.5
Millet	Whole grain	8.5

Strengths of the Whole-Grain Health Claims

Based on scientific evidence, including epidemiological studies and experimental clinical studies, the nutritional importance and health benefits of whole grains as part of a varied diet, is well documented, and further evidence is accumulating. Many health professionals adhere to this advice and attribute various health benefits to whole grains. The exact mechanisms of the efficacious effects brought about by the consumption of whole grains are less well understood. However, dietary fiber and phenolic compounds are frequently cited as the major functional-food

Table 3 Nutrient composition of whole-grain and refined wheat and rice, expressed as the mass of the nutrient per 100 g of grain at its normal moisture content

Nutrient	*Wheat wholemeal*	*Wheat flour*	*Brown rice flour*	*White rice flour*
Protein (g)	13.6	10.2	7.2	6.0
Fat (g)	1.8	1.0	2.7	1.4
Dietary fiber (g)	12.1	2.7	4.6	2.4
Ash (g)	1.2	0.5	1.5	0.6
Thiamin (mg)	0.45	0.12	0.44	0.14
Riboflavin (mg)	0.22	0.04	0.08	0.02
Niacin (mg)	6.3	1.2	6.3	2.6
Pantothenic acid (mg)	1.0	0.44	1.6	0.8
Vitamin B_6 (mg)	0.33	0.04	0.73	0.44
Potassium (mg)	403	106	287	76
Calcium (mg)	33	17	10	10
Iron (mg)	4	1	1.9	0.4
Phosphorus (mg)	343	106	333	96
Zinc (mg)	3	1	2.4	0.8
Magnesium (mg)	135	23	112	36

Values (taken from **Appendix**: Grain Composition Tables) are indicative, varying above or below these figures depending on the genotype and growth environment for the grains.

ingredients that are most likely to be responsible. Based on the volume of consumption and dietary fiber content, grains are among the foods that provide the highest amounts of dietary fiber.

There is a long history of dietary fiber as a healthy food ingredient. The proposed health benefits of dietary fiber probably exceed that of other functional-food ingredients. The NAS recently established dietary reference intakes for dietary fiber, giving figures of $38\,\mathrm{g\,day^{-1}}$ for men and $25\,\mathrm{g\,day^{-1}}$ for women. Median intakes of dietary fiber in the US diet for men and women are currently 17 and $13\,\mathrm{g\,day^{-1}}$, respectively. Since whole-grain-based foods are among the most significant food sources of dietary fiber, increased consumption of whole grains has the greatest potential to help consumers meet the recommended dietary reference intakes. However, a heavy diet of whole-grain foods could become monotonous. The existing whole-grain foods health claim has merit because it is an important first step in public-health policy to inform the consumer and promote the consumption of whole-grain foods.

Limitations of the Whole-Grain Health Claims

Limitations on claims for whole-grain benefits mainly focus on regulatory aspects of the topic. They center on:

- the lack of an overall definition for whole grain;
- the lack of whole-grain identification for cereals and other grains;
- the specification that a whole-grain food must contain 51% or more of one whole-grain ingredient by weight per reference amount customarily consumed; and
- that a whole grain must contain 11% dietary fiber.

The original authoritative statement of the NAS covered a broad array of plant foods, not simply whole cereals or whole wheat. To authorize the whole-grain health claim, the FDA used dietary fiber as the marker or index for a standard of compositional identity. However, the FDA has not established a definition for a whole grain. A clear standard of identity for a whole-grain status is not known for cereals listed in Table 1.

Maize, rice, and wheat are the three most abundant cereals produced in the world and their annual production is approximately equivalent. Whole wheat is a common term and relatively well-perceived among scientists and consumers as being the kernel with its bran covering, complete with germ, aleurone layer, and endosperm. Ground and/or cracked whole wheat can be used to make many foods with high consumer acceptance. Wheat flour of normal extraction rate (~76–80%) contains a low level of bran and aleurone layer. Flour of 72% extraction rate would be considered to be relatively low in flour yield commercially; it would be considered to contain virtually no bran and a minimum amount of aleurone layer. One commercial method of reconstituting "whole-grain flour" is to add wheat bran back to low-extraction flour, but this does not provide the full range of tissues that constitute whole wheat.

Whole-grain forms of corn (maize) are common in the diet of many cultures. In western diets, corn-on-the-cob and canned whole kernel corn ("sweet corn") contains ~11% total dietary fiber, but is generally classified as a vegetable and not a cereal. In the original petition to the FDA, popcorn was mentioned as a potential source of whole grain. Popcorn contains an average 12% dietary fiber. However, these forms of whole grain do not make major contributions to the western diet. Possibly more significant are breakfast cereals, such as corn flakes (*see* **Cereals**: Breakfast Cereals), but in this case, the raw material is primarily the endosperm of the corn kernel. Nevertheless, corn flakes do contain a significant level of dietary fiber, primarily in the form of arabinoxylans and resistant starch (*see* **Cereals**: Chemistry of Nonstarch Polysaccharides).

What constitutes whole rice and what fractions are included? Rice is usually steamed, but nutritional considerations depend on whether it is white rice or brown rice that is consumed, the latter being perceived as "healthier." White rice cannot be described as a whole grain, because the outer bran and aleurone layers have been removed.

For the purposes of the whole-grain foods health claim, "whole-grain foods" are those that contain 51% or more of whole-grain ingredients. The current whole-grain health claim is applied most often to wheat. Although food manufacturers may not rush to produce whole-grain foods from corn, sorghum, millet or rye cereals, there should be a method to allow mixtures of different grains, which could use the whole-grains health claim as an incentive for increased sales and greater variety among components in a whole-grain food. Once the identity of individual, whole cereals is established, some compromise can be used to set the level (percent) of a mixture that can constitute a whole-grain food product.

Conclusions

The health benefits of all foods are replacing the importance of nutrient content in the eyes of the consumer. Nutrient content claims, health claims, and

health messages (i.e., structure/function claims and logos) help the consumer seek and compare the nutritional quality and health benefits of foods. Nutrient-content claim descriptors ("high," "low," "no") help the consumer select which foods are a good source of some nutrient. Alternatively, these messages help them to refrain from eating too much of some food components (sodium, saturated fat, cholesterol). Scientific evidence for the health benefits of whole grains is accumulating. The chemical composition of whole-grain cereals indicates that they are high in dietary fiber, some vitamins and minerals, with the further advantage of having an abundance of phenolic compounds compared to other foods. To obtain these functional-food ingredients will require a varied diet and a diet that includes various grains. Nevertheless, it must be emphasized that foods made predominantly from refined grains also provide good nutrition, compared to many competing foods.

Consumers can expect to see increased efforts by food processors to provide a greater variety of whole-grain products. The allowances for the current health claim for whole-grain foods, as defined by the FDA, are discriminatory as it promotes the consumption of one cereal over other grains. The limitations of the current whole-grain foods health claim must provide opportunities to change the claim and make everyone more aware of whole grains and their important to health. There can be a health gain from the consumption of all grains. While whole grains are preferable in the diet, this does not discount the nutritional value and health benefits of all ingredients in grain-based foods (including white rice, noodles, pasta, and white bread).

APPENDIX 1

Grain Composition Table

S F Schakel, University of Minnesota, Minneapolis, MN, USA
N Van Heel and J Harnack, University of Minnesota, Minneapolis, MN, USA

The grain nutrient composition table developed by the Nutrition Coordinating Center (NCC) at the University of Minnesota contains values compiled from scientific literature, the USDA Nutrient Database for Standard Reference, manufacturer's information, and estimated data. The data in the table include both analytic and estimated values. (For further information regarding specific values, contact The Nutrition Coordinating Center, Division of Epidemiology, School of Public Health, 1300 South Second Street, Suite 300, Minneapolis Minnesota 55454-1015.) Estimated values were derived from (1) a different form of the same food (e.g., raw to cooked), (2) a similar food, or (3) calculation of recipes or formulations.

APPENDIX 2

Foods for Celiac Diets

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

Adherence to a gluten-free diet is the primary management strategy for anyone with celiac disease, dermatitis herpetiformis, or with any other form of gluten intolerance (*see* **Celiac Disease**). However, it is very difficult to be sure which foods are gluten free, except for certain products that are specifically labeled as being free of gluten, as is indicated by the gluten-free symbol (Figure 1).

This appendix provides a list of food ingredients, indicating which of them fall into one of the four categories indicated. The use of this list should thus assist in formulating a gluten-free diet through the use of ingredient labels on food products. These labels are listed and explained in Table 1.

Throughout this appendix, the term "gluten" refers to those proteins that cause celiac disease, the storage proteins of the grains of wheat, and of related cereal species, namely, rye, triticale, barley, and oats (*see* **Cereals**: Overview; Protein Chemistry. **Gluten and Modified Gluten**).

Use of this List

This list has been compiled by the Coeliac Society of Australia Inc., and it is reproduced here with permission. (The list does not come with any recommendations from this society on what is a "safe level" of gluten in the diet for celiacs. This list of food ingredients has been compiled in good faith from information available to the Coeliac Society of Australia Inc., which is a voluntary organization and is not a medical or professional body. The Society makes no recommendation as to its use and does not accept any responsibility for its use or misuse.)

The Coeliac Society of Australia Inc. believes that ideally, gluten should be entirely removed from the celiac diet, but that individual celiacs should consult their dietitian or doctor. To be labeled "gluten free" in Australia and New Zealand, a food must contain "no detectable gluten" by the most sensitive universally accepted test method. Current testing can achieve a detection level of 0.001–0.002% (10–20 ppm). Below this detection level, a food can be labeled "gluten free." The gluten content should then be included in the nutrition information panel on the product and be indicated as zero or not detected. Sometimes, foods labeled "gluten free" may contain ingredients that would otherwise be of concern, e.g., maltodextrin from wheat. In these circumstances, the gluten-free label overrides the ingredient listing on the food because either the individual ingredient or the final product is gluten free.

Many food additives are indicated by an international system of numbers. These may include colors, flavors, or flavorings, and they can include other substances as carriers, e.g., maltodextrin, starch, and dextrose in dry products. In Australia and New Zealand, they are identified if coming from a gluten-containing grain. Flavors used in candies, drinks, and ice cream are almost certainly gluten free. The additives maltitol – hydrogenated glucose syrup (965), caramel color (150), and amylase (1100) may possibly originate from gluten-containing grains, but they have been tested to contain "no detectable gluten." Monosodium glutamate (621) and other glutamates (620, 622, 623, 624, 625) may be derived from glucose syrup.

With respect to alcoholic beverages, advice to celiacs in Canada and the USA is to avoid all alcohol and alcoholic beverages derived from wheat or rye. This includes distilled products such as whisky, some vodka, and gin. As distillation is a recognized method of purification, clear distilled liquids (e.g., white vinegar, ethyl alcohol, and spirits) are regarded as gluten free in the following list. Alcoholic beverages are in

Figure 1 The gluten-free symbol, an ear of wheat crossed out.

Table 1 Ingredients list

The following ingredient labels are used on food products:

√ gluten free,
X contains gluten,
☐ can sometimes be manufactured from or contain ingredients derived from a gluten-containing grain, and
☑ no detectable gluten even if derived from a gluten-containing grain.

A

√	Acacia gum (gum arabic)
√	Acetic acid
√	Agar agar
√	Albumen
X	Ale
√	Alfalfa sprouts
√	Algin (alginic acid)
√	Allspice
√	Almonds
√	Alpha tocopherol acetate
√	Amaranth
☑	Amylase
√	Anchovies
√	Anchovy extract
√	Anti-caking agents*

* "anti-caking agents" do not normally contain gluten. On occasions a modified starch may be used. The term anti-caking agent should then be followed in brackets by a number in the 1400 series or the name "modified starch."

√	Antioxidants
√	Apple
√	Apple juice
√	Apple puree
√	Apricot
√	Arrowroot
√	Artichokes
√	Artificial sweetener
√	Artificial sweetening substances
√	Ascorbic acid
√	Asparagus
√	Aspartame
√	Aspic
X	Atta
√	Aubergine (eggplant)

B

√	Bacon*
√	Bacon (smoked)*

* Bacon may contain glucose syrup/dextrose – check ingredients.

☐	Baking powder
√	Bamboo shoots
√	Banana
√	Banana extract
X	Barley
X	Barley flakes
X	Barley (malt)
X	Barley (pearl)
√	Basil
X	Batter (unless labeled "gluten free")
√	Bay leaf
√	Beans
√	Beans (borlotti)
√	Beans (broad)
√	Beans (butter)
√	Beans (garbanzo)
√	Beans (kidney)
√	Beans (lima)
√	Beans (navy)
√	Beans (pinto)
√	Beans (red kidney)
√	Beans (wax yellow)
√	Beans sprouts
√	Beef
√	Beef extract
√	Beef fat
☐	Beef stock
√	Beef tallow
X	Beer
√	Beeswax
√	Beetroot
√	Besan
√	Beta-carotene
☐	Beverage whitener
√	Bicarbonate of soda
√	Biotin
√	Bitters
√	Black bean
√	Black currant
√	Blackberry
√	Boysenberry
√	Brains
X	Bran (wheat, oat, barley)
√	Bran (rice)
☑	Brandy*

* May contain caramel color.

√	Brazil nuts
X	Brewers yeast
√	Broccoli
√	Bromelain
√	Brussel sprouts
X	Bucatini
√	Buckwheat (kasha)
√	Buckwheat flour
X	Burghul (bulgar, bulgur, bulghur)
√	Butter
√	Butter oil
√	Buttermilk solids

C

√	Cabbage
√	Caffeine
√	Calamari (no flour or batter)
√	Calcium carbonate
√	Calcium caseinate
√	Calcium cyclamate
√	Calcium hydrogen phosphate
√	Calcium pantothenate
√	Canola oil
√	Capers
√	Capsicum
☑	Caramel color
√	Caraway
√	Carbonated water

Table 1 Continued

√	Carboxymethyl cellulose (CMC)
√	Cardamom
√	Carmine
√	Carnauba wax
√	Carob
√	Carob bean gum
√	Carob powder
√	Carrageenan
√	Carrots
√	Carrot juice
√	Casein
√	Cashews
√	Cassava (manioc)
√	Cassia (oil)
√	Cayenne pepper
√	Celery
√	Celery root powder
√	Celery juice
√	Cellulose
X	Cereal (wheat, rye, barley, and oats)
√	Champignons
√	Channa
√	Cheese
√	Cheese (blue)
√	Cheese (cheddar)
√	Cheese (cottage)
√	Cheese (fetta)
√	Cheese (mozzarella)
√	Cheese (neufchatel)
√	Cheese (parmesan)
√	Cheese (romano)
☐	Cheese flavor
√	Cheese powder
√	Cherries
√	Cherries (black)
√	Cherries (glace)*
√	Cherries (imitation)*
	* May contain glucose syrup.
√	Cherry paste
√	Chickpea
√	Chicken
√	Chicken fat
☐	Chicken flavor
☐	Chicken powder
☐	Chicken stock
√	Chicory
√	Chilli
√	Chilli powder
√	Chives
√	Chlorophyll
√	Chocolate
√	Chocolate (milk)
√	Chocolate (dark)
√	Chocolate bits
√	Cholecalciferol
☐	Chutney
☑	Cider*
	* May contain caramel color.
√	Cinnamon
√	Citric acid
√	Citrus juices
√	Citrus peel*
	* May contain glucose syrup.
√	Clams
√	Cloves
√	Cocoa
√	Cocoa butter
√	Cocoa fat
√	Cocoa liquid
√	Cocoa mass
√	Cocoa powder
√	Coconut
√	Coconut (desiccated)
√	Coconut cream
√	Coconut milk
√	Coconut oil
√	Cod liver oil
√	Coffee
☑	Cognac*
	* May contain caramel color.
√	Cointreau
√	Colors*
	* "Colors" may contain certain diluents including starch and dextrose. However, this is not common and colors are used at very low levels.
√	Compounded chocolate
√	Condensed milk
☐	Confectionery
☐	Confectionery sprinkles
√	Copha
√	Copper sulfate
√	Coriander
√	Corn
√	Cornstarch
√	Corn gluten (term used in the USA)
√	Corn grits (maize)
√	Corn solids
√	Corn syrup
√	Corn syrup (solids)
☐	Corn flakes
√	Corn flour (maize)
X	Corn flour (wheat)
√	Corn meal (maize)
√	Cottonseed oil
X	Couscous
√	Crab
√	Cream (powder, light, sour, thickened)
√	Cream of tartar
√	Cucumber
√	Culture (e.g., acidophillus)
√	Cumin
√	Currants
☐	Curry powder
√	Cyanocobalamin
√	Cyclamate
D	
√	Dal (dhal)
√	Dasheen (eddo)
√	Dates
X	Dextrin (wheat)
√	Dextrin (maize)
☑	Dextrose
☑	Dextrose monohydrate
√	Dibasic calcium phosphate
√	Dill
☐	Dill pickle

Table 1 Continued

The following ingredient labels are used on food products:

- √ gluten free,
- X contains gluten,
- ☐ can sometimes be manufactured from or contain ingredients derived from a gluten-containing grain, and
- ☑ no detectable gluten even if derived from a gluten-containing grain.

- √ Dill seeds
- X Dinkel (spelt)
- X Durum wheat

E

- √ Egg
- √ Eggplant
- √ Egg albumin
- √ Egg liquid
- √ Egg powder
- √ Egg white
- √ Egg white powder
- √ Egg yolk
- √ Egg yolk powder
- √ Elderberry juice
- √ Emulsifiers
- ☑ Enzyme amylase
- √ Ethyl alcohol*

* Ethyl alcohol may be produced from wheat but is distilled.

- √ Ethyl maltol
- √ Ethyl vanillin

F

- X Farina
- √ Fat (animal, vegetable)
- √ Fenugreek
- √ Ferrous sulphate
- √ Figs
- √ Fish
- ☐ Flavors*

* "Flavor" and "natural flavor" may include carriers; in dry products, maltodextrin, starch or dextrose can be used. In savory products, flavors may be derived in part from the hydrolysis of cereals. Sweet flavors used in ice cream, drinks, candies, etc., should be gluten free.

- ☑ Flavor enhancers (see monosodium glutamate)
- √ Flax
- √ Flax seeds
- X Flour (barley)
- X Flour (oat)
- X Flour (plain)
- X Flour (rye)
- X Flour (self raising)
- X Flour (spelt)
- X Flour (wheat)
- X Flour (wholemeal)
- √ Flour (amaranth)
- √ Flour (buckwheat)
- √ Flour (potato)
- √ Flour (rice)
- √ Flour (soy)
- √ Flour (tapioca)
- √ Flour treatment agents
- ☐ Fondant
- √ Food acids
- ☑ Fructose
- ☑ Fructose syrup
- √ Fruit (dried mixed)*
- √ Fruit (glace)*

* May contain glucose syrup.

- √ Fruit juice concentrate
- √ Fruit pulp
- √ Fruit sugar syrup

G

- √ Galangal root
- √ Garlic
- √ Garlic powder
- √ Gelatine
- ☐ Gherkin
- ☐ Gherkin relish
- √ Gin*

* Distilled from fermented grains.

- ☑ Ginger
- ☑ Glucono delta lactone
- ☑ Glucose
- ☑ Glucose powder
- ☑ Glucose syrup
- ☑ Glucose syrup (dried)
- X Gluten
- √ Glycerin
- √ Glycerol
- √ Glycine
- √ Golden syrup
- X Graham flour
- √ Gram (chickpea)
- √ Grapefruit (juice)
- √ Grape juice
- √ Guar gum*

* May have laxative effect (unrelated to gluten).

- √ Guava
- √ Guava juice
- √ Gum arabic (acacia gum)

H

- √ Ham
- ☐ Ham (manufactured)
- √ Hazelnuts
- √ Herbs
- √ Herring
- √ Hominy (hominy grits)
- √ Homous (hummus, hommous)
- √ Honey (powder)
- ☐ Honey crumble pieces
- √ Hops
- √ Horseradish (extract)
- √ Hydrolyzed protein (maize, soy)
- √ Hydrolyzed grain protein (maize, soy)
- √ Hydrolyzed plant protein (maize, soy)
- √ Hydrolyzed vegetable protein (maize, soy)
- X Hydrolyzed wheat protein

I

- √ Icing sugar mixture (from maize starch)
- X Icing sugar mixture (from wheat starch)

Table 1 Continued

√	Icing sugar (pure)
√	Inulin
√	Invert sugar
√	Invert syrup
√	Invertase
√	Iron
√	Iron pyrophosphate
√	Isomalt
J	
√	Job's tears (millet)
K	
√	Karaya gum
√	Kasha (buckwheat)
X	Kawmut (polish wheat)
√	Kippers
√	Kiwi fruit
√	Kudzu
X	Kumat®
L	
√	Lactase
√	Lactic acid
√	Lactose
X	Lager
√	Lamb
√	Lard
√	L-carnitine
√	L-cystine
√	L-cysteine
√	Lecithin
√	Leeks
√	Legumes
√	Lemon essence/oil
√	Lemon juice concentrate
√	Lemons
√	Lentil flour
√	Lentils
√	Lettuce
☐	Licorice
√	Licorice extract
√	Lima beans
√	Lime
√	Linoleic acid
√	Linseed
√	Linseed oil
☑	Liqueur*
	* May contain caramel color.
√	L-methionine
√	Lobster
√	Locust bean gum (carob bean)
√	Loganberry
√	Lupin
√	Lupin fiber
√	Lychees
M	
√	Macadamia
√	Macaroni (rice)
X	Macaroni (wheat)
√	Mackerel
√	Maize (flour)
X	Malt
X	Malt extract
X	Malt flavoring
X	Malt sugar/syrup
X	Malt vinegar
X	Malted milk
√	Maltodextrin (maize, potato, tapioca)
X	Maltodextrin (wheat)*
	* The gluten level in wheat maltodextrin is very low. On occasions gluten may be not detectable.
√	Maltol
☑	Maltitol (hydrogenated glucose syrup)
☑	Maltose
√	Mandarin (juice)
√	Manganese sulphate
√	Mango
√	Manioc (cassava)
√	Mannitol
☐	Manufactured ham/meat
√	Margarine
√	Marjoram
☑	Marsala wine*
	* May contain caramel color.
☐	Marzipan
☐	Mayonnaise
√	Meat
☐	Meat (processed)
√	Melon
√	Menthol
√	Methyl cellulose
√	Milk
√	Milk (curd)
√	Milk (full cream)
√	Milk (skim, skim concentrate)
√	Milk (skim dried)
√	Milk fat
√	Milk protein
√	Milk solids
√	Millet
√	Millet meal
√	Mineral oils
√	Mineral salts
√	Mineral water
√	Mint
√	Mint essence
√	Mint flakes
√	Mint leaves
√	Modified starch (corn, maize, potato, tapioca)
X	Modified starch (wheat)
√	Molasses
√	Monoglyceride
X	Monosodium glutamate (MSG) (if from wheat)
√	Mushrooms
√	Mussels
√	Mustard (pure)
☐	Mustard (prepared)
√	Mustard flour
√	Mustard seed
√	Mutton
N	
√	Niacin
√	Niacinamide

Table 1 Continued

The following ingredient labels are used on food products:

√ gluten free,
X contains gluten,
☐ can sometimes be manufactured from or contain ingredients derived from a gluten-containing grain, and
☑ no detectable gluten even if derived from a gluten-containing grain.

√	Noodles/egg noodles (rice)
X	Noodles/egg noodles (wheat)
√	Nori
√	Nutmeg
√	Nuts
√	Nuts (plain)
☐	Nuts (dry roasted)
√	Nuts (mixed)
O	
X	Oatmeal
X	Oats
X	Oats (rolled)
X	Oat bran
X	Oat flour
X	Oat gum
√	Olives (black, green)
√	Onion
√	Onion (green)
√	Onion (kibbled)
√	Onion juice
√	Onion powder
√	Orange
√	Orange juice concentrate
√	Oregano
√	Oregano flakes
√	Oyster juice extract
☐	Oyster sauce
√	Oysters (smoked)
P	
√	Palm oil
√	Papain
√	Papaya
√	Papaya juice
√	Paprika
√	Parsley
√	Parsley juice
√	Parsnip
√	Passionfruit
√	Passionfruit juice/concentrate
√	Pasta (corn, rice)
X	Pasta (unless labeled gluten free)
√	Paw paw
√	Paw paw puree
√	Pea juice
√	Peaches
√	Peach juice/puree
√	Peanuts
☐	Peanuts (dry roasted)
√	Peanut butter*
	* May contain glucose syrup or maltodextrin.
√	Peanut oil
√	Pear juice
√	Pears
√	Peas (besan)
√	Peas (channa)
√	Peas (chick)
√	Peas (garbanzo)
√	Peas (gram)
√	Peas (green)
√	Peas (split)
√	Peas (yellow)
√	Pecan nuts
√	Pectin
√	Peel (mixed)*
	* May contain glucose syrup.
√	Pepper (black)
√	Pepper (white)
√	Pepper extract
√	Peppercorns
√	Peppermint oil
☐	Pepperoni
√	Peppers
√	Peppers (chilli)
√	Peppers (green)
√	Peppers (hot)
√	Peppers (jalapeno)
√	Peppers (red)
√	Phylloquinone
☐	Pickles
X	Pilcorn (oats)
√	Pimento
√	Pine nuts
√	Pineapple
√	Pineapple juice concentrate
√	Plum pulp
√	Plum puree
√	Plums
√	Poi (fermented taro)
√	Polenta
√	Polydextrose*
	* Manufactured in the USA from dextrose and sorbitol. Cereal origins almost certainly maize.
√	Poppy seeds
√	Pork
√	Pork livers
☑	Port*
☑	Port wine*
	* May contain caramel color.
X	Porter
√	Potassium iodate
√	Potato (dried instant mashed)
√	Potato flour
√	Potato granules
√	Potato starch
√	Potatoes
√	Praline
√	Prawns
√	Preservatives
√	Propellants
√	Protease enzyme
√	Prunes/juice
√	Psyllium

Table 1 Continued

√	Pulse fiber
√	Pyridoxine hydrochloride
Q	
√	Quince
√	Quinine
√	Quinoa
R	
√	Radish
√	Rapeseed
√	Raspberry
√	Red currant
√	Rennet
√	Riboflavin
√	Ribonucleotides
√	Rice
√	Rice beverages*
√	Rice bran
√	Rice cereal
√	Rice extract*
√	Rice ground/flour/starch
√	Rice noodles
√	Rice syrup*
	* May be manufactured using amylase derived from malted cereals – residual gluten traces seem unlikely.
√	Rice vermicelli
√	Rice (glutinous)*
	* Despite the similar sounding term, this does not contain gluten.
√	Rice (malted)*
	* May be manufactured using amylase derived from malted cereals – residual gluten traces seem unlikely.
√	Rice (wild)
√	Rockmelon
√	Rose hip juice
√	Rosemary
☑	Rum*
	* May contain caramel color
X	Rye
X	Rye flour/meal
☑	Rye whisky*
	* May contain caramel color.
X	Rye (kibbled/sour)
S	
√	Saccharin
√	Saffron
√	Sago
☐	Salami
√	Salmon
√	Salt
√	Sardines
☐	Sauces
√	Sauerkraut
X	Sausages (unless identified as gluten free)
√	Sausages (gluten free)
☑	Scotch whisky*
	* May contain caramel color.
☐	Seasoning
√	Seaweed
X	Semolina
√	Sesame
√	Sesame meal
√	Sesame seeds
√	Shallots
☑	Sherry*
	* May contain caramel coloring.
√	Shortening
√	Shortening (vegetable)
√	Shrimp
√	Shrimp paste
☐	Shrimp powder
√	Snow peas
☐	Soba noodles
√	Sodium acid pyrophosphate
√	Sodium bicarbonate
√	Sodium caseinate
√	Sodium citrate
√	Sodium metabisulphite
√	Sodium molybdate
√	Sodium nitrate
√	Sodium nitrite
√	Sorbic acid
☑	Sorbitol
√	Sorghum
X	Sour dough (unless identified gluten free)
√	Soy bran
√	Soybeans
√	Soy fiber
√	Soy flour
√	Soy grits
√	Soy isolate
☐	Soy milk (soy drink, soy beverage)
√	Soy protein
☐	Soy sauce
X	Spaghetti (unless labeled gluten free)
√	Spaghetti (corn, rice)
√	Spearmint oil
X	Spelt (dinkel or German wheat)
√	Spice extract
√	Spice oils
√	Spices (pure)
√	Spinach
√	Spinach powder
√	Spirit (fermented)
√	Starch (corn, modified corn, pregel corn)
√	Starch (maize, modified maize, pregel maize)
√	Starch (potato, modified potato, pregel potato)
√	Starch (tapioca, modified tapioca, pregel tapioca)
X	Starch (wheat, modified wheat, pregel wheat)
☐	Stock
√	Strawberry
√	Sucralose
√	Sucrose
√	Suet
√	Sugar
√	Sugar (brown)
√	Sugar (caramelized)
√	Sugar (caster)
√	Sugar (icing) (pure)
√	Sugar (icing/mixture – maize, corn, rice starch)
X	Sugar (icing/mixture – wheat starch)
√	Sugar (inverted)
√	Sultanas
√	Sunflower oil/seeds

Table 1 Continued

The following ingredient labels are used on food products:

√	gluten free,
X	contains gluten,
☐	can sometimes be manufactured from or contain ingredients derived from a gluten-containing grain, and
☑	no detectable gluten even if derived from a gluten-containing grain.

√	Swede
√	Sweet potato
√	Sweetener
☐	Szechuen sauce
T	
√	Tallow
√	Tallow (beef refined)
☐	Tamari
√	Tamarind
√	Tapioca (flour)
√	Taro (dasheen, eddo)
√	Tartaric acid
√	Taurine
√	Teff
√	Textured vegetable protein (soy)
X	Textured vegetable protein (wheat)
√	Thiamin (hydochloride)
√	Thickener (including 1400–1450)* (corn, maize, potato, tapioca)
X	Thickener (including 1400–1450)* (wheat)
	* The number on the thickener indicates how the starch is processed not the source.
√	Thyme
√	Tofu
√	Tomato juice/paste/powder
√	Tomatoes
√	Tragacanth gum
√	Treacle
√	Triglycerides
X	Triticale
√	Tuna
√	Turkey
√	Turkey meat (unprocessed)
√	Turmeric
√	Turnip
U	
√	Urd (urad)

http://www.nippin.co.jp – Nippon Flour, Japan.
http://www.nisshin.com – Nisshin Flour Milling, Japan.
http://www.ocrim.com – Ocrim, headquartered in Italy, markets milling, handling, and automation equipment. Ocrim also have a Milling Training Centre which offers vocational training. The webiste describes all of Ocrim's equipment.
http://www.ohiocorn.org – Ohio Corn Marketing.
http://www.peanutsusa.com – The American Peanut Council.
http://www.pos.ca – A description of improved methods for canola processing to give higher-quality meal may be found at this website.
http://www.pulseaus.com.au – This site provides information on production, breeding, and marketing of pulse crops in Australia and has links to other Australian institutions involved in pulse research.
http://www.pulseaus.com.au – R&D undertaken on chickpea in Australia: management and marketing.
http://www.quakeroats.com – Quaker Oats Co.
http://www.remy-industries.be – Based in Belgium, Remy Industries is the world's largest producer of rice starch. General information on rice derivatives is presented on the website.
http://www.ricebranoil.biz – Rice Bran Oil.
http://www.riceland.com – Riceland Foods in Stuttgart, AR, USA.

http://www.saitoku.com – A Japanese site all about okara and its use as a food.
http://www.sake.nu – A site all about saké and where you can buy to suite your taste.
http://www.saskpulse.com – This website is maintained by Saskatchewan Pulse Growers. It has information on production and marketing of pulse crops. This site is updated regularly.
http://www.satake.co.uk – Satake UK Division. Satake (http://www.satake.com) is headquartered in Japan. For information in English, the Satake UK Division site is recommended. Satake have long been established as a leader in rice milling equipment, and entered the wheat milling equipment market in the 1990s. They were the first company to aggressively market preprocessing equipment for wheat milling under the brand name "Peritec."
http://www.solae.com – DuPont Protein Technologies, St. Louis, MO, USA.
http://www.sosland.com – Sosland Publishing Co., publishers of several useful trade magazines and baking science & technology.
http://www.soylife.com – Schouten USA, Minneapolis, MN, USA.
http://www.starchaust.com.au – Penford starches, Australia.
http://www.statpub.com – Worldwide market and production information on chickpea.
http://www.sv-m.com.
http://www.tepral-fr.com – Tepral, Strasbourgh, France.
http://www.tortilla-info.com – Tortillas Industry Association (2003) website provides information on member companies, current activities, and some educational materials.
http://www.unipi-pasta.it – This website gives useful information on economic aspects of pasta (in Italian).
http://www.wensfood.com – The site of Wensfood offering soy products for sale in the United States of America.
http://www.westonmilling.com.au – Weston Foods, Australia.
http://www.world-grain.com – The Sosland Publishing Company website contains a "focus" series that gives detailed information on wheat production in many countries.
http://www.zeochem.com – Zeochem is a major producer of molecular sieve adsorbents. Its US headquarter is located in Louisville, KY. This website describes the types of molecular sieves and molecular sieve adsorbents (crystalline alumino-silicates) with applications in ethanol dehydration.

APPENDIX 4

Test Methods for Grain and Grain-Based Products

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The great breadth of topics in grain science is indicated within this encyclopedia. For virtually all of these topic areas, there is the need for laboratory test methods to evaluate the quality characteristics of the grains produced and to monitor the processing quality of the final products that result. This appendix lists the many methods that have been devised to provide these testing requirements. The methods listed are those developed and published by two major associations of grain scientists:

- The American Association of Cereal Chemists (AACC) is based in St. Paul, MN, USA, with a worldwide membership of ~4000 scientists who have interests in the grain-based food industry.
- The International Association for Cereal Science and Technology (ICC), based in Vienna, Austria, is an international association committed to international cooperation through disseminating information and developing standard methods for the well-being of all people.

In addition, standard methods of grain testing have been developed by several other organizations, including the following. The interested readers are referred to their publications or websites (listed at the end of this text) for further details (*see* **Scientific Societies Associated With Grain Science**).

- The American Oil Chemists' Society (AOCS) comprises nearly 5000 members worldwide, providing "a global forum for the science and technology of fats, oils, surfactants, and related materials."
- The International Seed Testing Association (ISTA) is a worldwide, nonprofit association whose main activity is to provide methods and services for the testing of seed moving in international trade.
- AOAC International is an "internationally recognized organization with ~120 years of experience in validating and approving analytical methods for foods and agriculture."
- The Cereal Chemistry Division of the Royal Australian Chemical Institute, based in Melbourne, Australia.
- The American Society of Agronomy (ASA) is "dedicated to the development of agriculture enabled by science, in harmony with environmental and human values. The Society supports scientific, educational, and professional activities to enhance communication and technology transfer among agronomists and those in related disciplines on topics of local, regional, national, and international significance."

Method Development

The development of these methods is a painstaking and laborious process. It may start with the realization that there is the need for a specific method of analysis; a group of researchers may study the best means of achieving the desired aim. It may take a year or two of research to achieve their initial goal. When they reckon that they have a viable method, they would probably describe it in a research article that is submitted to a suitable scientific journal.

This might be a journal that covers topics of grain science, such as *Cereal Chemistry* and *Cereal Foods World* (both published by the AACC), or the *Journal of Cereal Science* (published by Elsevier Science, UK). Alternatively, they may choose to submit their paper to a journal that deals more broadly with food science or agriculture, or more specifically with analytical methodologies. On receipt of their research article, the editorial staff of the journal would send out the manuscript for "peer review," i.e., the paper is sent for critical assessment separately by two or more independent scientists who are recognized experts in the specific field covered by the paper. Depending on the opinions of these referees, the editorial staff may accept the article for publication; alternatively, it may be rejected, or it may be returned to the authors for revision until it is acceptable for publication.

Following the publication of the new method, other research groups may read it and realize its value, evaluating it as a procedure that would suit their analytical needs. If they find it suitable, they might add some improvements of their own. These other research groups might communicate with the original group of scientists, suggesting the need for collaborative evaluation of the method, either in its original or

modified format. A common forum for such collaborative evaluation is provided within associations of scientists with common interests, such as the AACC or ICC. Regular scientific meetings of the associations provide additional opportunities for the exchange of ideas and for arranging collaborative development of methods.

A further step in the formal development of a method comes when there is agreement on the need for the method, on a draft procedure, and on a process for collaborative evaluation of the draft method. This process would probably involve the provision of a set of relevant samples for distribution to all the laboratories involved. Results obtained by applying the draft procedure to these samples would be provided to a central coordinator for statistical evaluation, using guidelines provided in ICC method 203 and in AACC method 78-60, for example. In this process, collaborators may find deficiencies in the method, reporting on these with recommendations for improvement. These iterative processes of collaboration and improvement may be repeated a few times until the various collaborators are satisfied that the method is optimized, and that it is thus ready for adoption as a "standard method" of the association involved. This final step of adoption may require the formal agreement of a meeting of the association.

Following adoption, the details of the method are added to the association's manual of standard methods. These manuals are updated from time to time as new methods are added, and as superseded methods are removed. The most up-to-date lists of standard methods are likely to be the respective websites, with the possibility that methods can be purchased individually from the website.

This general process of method development has been followed, in some form or other, for the methods listed in this appendix (see Tables 1 and 2). Inevitably, there is some duplication between associations in the methods developed. In some cases, the method developed by one organization is adopted (possibly after modification) by another organization. In addition, lists of approved methods are likely to be developed by individual research or analytical laboratories or companies.

The Range of Methods

The diversity of methods listed below covers the analysis of grains and of grain-based products. Additional to these are the many more analytical procedures needed for the earlier stages of grain production, such as soil and plant testing. Further details of these agronomic needs can be accessed on relevant websites and via "Further Reading" below.

Grain Testing after Harvest

The methods listed below cover all the requirements of quality control from harvest through to the final production of the food or feed product. An essential initial step at any of these stages is the act of taking a sample. If the samples taken for analysis are not representative of the consignments that have been sampled, then there is little point in performing the required analyses. At least, there must be an awareness of the relationship of the sample for testing to the whole consignment that it is intended to represent. For the recommended sampling procedures, see ICC standard methods 101, 120, 130, and 138, and AACC methods grouped under 64.

In the sequence of grain production and processing, the analysis of the harvested grain comes first. Initial tests involve the determination of bulk density (as "bushel weight" in AACC method 55-10) and of nongrain material, called "extraneous matter" in the AACC methods (group 28) and as "besatz" in ICC methods 102 and 103. Grain analysis also involves determination of possible defects, such as the production of mycotoxins (AACC method group 45).

Another potential defect is the extent to which rain at harvest has triggered the production of the starch-degrading enzyme, α-amylase (*see* **Cereals**: Grain Defects). This may be determined by the range of methods listed in the ICC suite as numbers 107, 108, 126, 161, and 162, or by AACC methods in the enzymes group (22). Why is there the need for several methods to apparently achieve the same result? In this case, the various methods are suited to different situations, namely, for use in the laboratory by determining the actual enzymic activity by colorimetric means (ICC method 126, AACC method 22-02), or methods that measure the effect of the α-amylase on the endogenous starch of the grain sample, either in the laboratory (as "falling number" in ICC method 107 and AACC method 56-81B) or when grain is received at the elevator (as "stirring number" in AACC method 22-08 and ICC method 161).

Chemical Composition

Next in importance is the chemical composition of the grain, involving moisture content for all grains, protein content for most grains, and oil content for the oilseeds. Routine analyses of these constituents generally involve near-infrared (NIR) spectroscopy (AACC method group 39 and ICC methods 159 and 202), but this procedure requires reference sets

Table 1 ICC standard methods

Acidity	
No. 145:	Determination of acidity (according to Schulerud) for cereals and cereal products
α-Amylase activity (enzymes)	
No. 107/1:	Determination of "falling number" according to Hagberg-Perten as a measure of the degree of α-amylase activity in grain and flour
No. 108:	Colorimetric method for the determination of α-amylase activity
No. 126/1:	Method for using the Brabender amylograph
No. 161:	Determination of the "stirring number" using the Newport Rapid Visco Analyzer, as a measure of the degree of α-amylase activity in grain and flour
No. 162:	Rapid pasting method using the Newport Rapid Visco Analyzer
Ash content	
No. 104/1:	Determination of ash in cereals and cereal products
No. 157:	Ash determination by conductivity
Baking test	
No. 131:	Baking test for wheat flours
Besatz	
No. 102/1:	Determination of besatz of wheat
No. 103/1:	Determination of besatz of rye
Carbohydrates	
Mono- and disaccharides	
No. 132:	Determination of saccharose in cereals and cereal products
Starch	
No. 122/1:	Determination of starch content by calcium chloride dissolution
No. 123/1:	Determination of starch content by hydrochloric acid dissolution
No. 128/1:	Procedure for the determination of starch after enzymic decomposition
No. 164:	Measurement of damaged starch by using MEGAZYME enzymatic kit
No. 169:	Method for using the Brabender viscograph
Durum wheat, semolina, flour, and pasta	
No. 129:	Method for determination of the vitreousness of durum wheat
No. 151:	Determination of the sedimentation value SDS test of durum wheat
No. 152:	Determination of the yellow pigment content of durum wheat semolina and flour
No. 153:	Determination of total organic matter (TOM) in pasta
No. 158:	Gluten index method for assessing gluten strength in durum wheat (*Triticum durum*)
Fat content	
No. 136:	Cereals and cereal products – determination of total fat content
Fiber (crude fiber, bran, dietary fiber)	
No. 113:	Determination of crude fiber value
No. 140:	Enzymic determination of the bran content of cereals
No. 156:	Determination of total dietary fiber
Gluten	
No. 106/2:	Working method for the determination of wet gluten in wheat flour
No. 137/1:	Mechanical determination of the wet gluten content of wheat flour (glutomatic)
No. 155:	Determination of wet gluten quantity and quality (gluten index according to Perten) of whole wheat meal and wheat flour (*Triticum aestivum*)
No. 158:	Gluten index method for assessing gluten strength in durum wheat (*Triticum durum*)
Heavy metals	
No. 141:	Determination of mercury in cereals
No. 154:	Determination of cadmium and lead in cereals and cereal products
Infrared analyses	
No. 159:	Determination of protein by near-infrared (NIR) reflectance spectroscopy
No. 202:	Procedure for near-infrared (NIR) reflectance analysis of ground wheat and milled wheat products (recommendation)
Microbiological tests	
No. 125:	Method of determining the count of aerobic mesophilic bacteria (plate count method)
No. 133:	Determination of the germ count of aerobic and facultatively anaerobic, mesophilic bacteria (plate count method) in cereals, cereal products, and animal feed
No. 134:	Determination of the fungus germ count (plate count method) in cereals, cereal products, and animal feed
No. 139:	Determination of fungus germ count (plate count method)
No. 144:	Enumeration of spores of mesophilic bacteria
No. 146:	Enumeration of yeasts and mold (spatula method)
No. 147:	Enumeration of bacteria (spatula method)
No. 206:	Microbiology – general guidance for microbiological examination (recommendation)

Table 1 Continued

Moisture content	
No. 109/1:	Determination of moisture content of cereals and cereal products (basic reference method)
No. 110/1:	Determination of moisture content of cereals and cereal products (practical method)
No. 135:	Determination of the water content of whole maize kernels
No. 201:	Test procedure for rapid moisture determination apparatus (recommendation)
Particle size	
No. 127:	Determination of the particle size distribution in flour by the Andreasen pipette method
Physical dough testing	
No. 114/1:	Method for using the Brabender extensograph
No. 115/1:	Method for using the Brabender farinograph
No. 121:	Method for using the Chopin alveograph
No. 126/1:	Method for using the Brabender amylograph
Protein content	
No. 105/2:	Determination of crude protein in cereals and cereal products for food and feed
No. 159:	Determination of protein by near-infrared (NIR) reflectance spectroscopy
No. 167:	Determination of crude protein in grain and grain products for food and feed by the Dumas combustion principle
Sampling	
No. 101/1:	Sampling of grains
No. 120:	Mechanical sampling of grain
No. 130:	Sampling of milling products (semolinas, flours, agglomerated flours, and by-products)
No. 138:	Mechanical sampling of milled cereal products
Sedimentation test	
No. 116/1:	Determination of sedimentation value (according to Zeleny) as an approximate measure of baking quality
No. 118:	Preparation of test flour from wheat samples for sedimentation test
No. 151:	Determination of the sedimentation value SDS test of durum wheat
Statistical evaluation	
No. 203:	Statistical analysis of the results of collaborative studies (recommendation)
Variety identification	
No. 143:	Wheat identification of varieties by electrophoresis
Vitamins	
No. 111:	Chemical assay of nicotinic acid in cereal products
No. 112:	Microbiological assay of nicotinic acid in cereal products
No. 117:	Chemical determination of thiamine in cereal products
No. 119:	Rapid method for the determination of thiamine in enriched flours and enrichment mixtures

Methods of the ICC are continuously revised and enlarged in accordance with recent needs and development. For additional information, contact the ICC Secretariat by e-mail or via the website.

Table 2 Tenth edition of AACC methods (including the 2002 supplement)

02 Acidity	
02-01A	Fat acidity – general method
02-02A	Fat acidity – rapid method, for small grains
02-03A	Fat acidity – rapid method, for corn
02-04A	Fat acidity – colorimetric method
02-31	Titratable acidity
02-32A	Neutralizing value of acid-reacting materials
02-52	Hydrogen-ion activity (pH) – electrometric method
04 Acids	
04-10	Phosphoric acid – qualitative method
04-11	Phosphoric acid – quantitative method
04-14	Sulfuric acid – quantitative method
04-20	Acetic, butyric, and lactic acids in rye flour
04-21	Benzoic acid
04-22	Citric and isocitric acids
04-27	Tartaric acid – quantitative method
04-28	Free or combined tartaric acid – qualitative method
06 Admixture of flours	
06-10	Admixture of rye and wheat flours
06-11	Soy flour

Table 2 Continued

07 Amino acids	
07-01	Measurement of acid-stable amino acids
07-11	Measurement of sulfur amino acids
07-20	Measurement of tryptophan – alkaline hydrolysis
08 Total ash	
08-01	Ash – basic method
08-02	Ash – rapid (magnesium acetate) method
08-03	Ash – rapid (2 h, 600°) method
08-10	Ash in cacao products
08-11	Ash in dry milk products
08-12	Ash in farina and semolina
08-14	Ash in molasses, sugars, and syrups
08-16	Ash in soy flour
08-17	Ash in starch
08-18	Ash in yeast foods
08-21	Prediction of ash content in wheat flour – near-infrared method
10 Baking quality	
10-05	Guidelines for measurement of volume by rapeseed displacement
10-09	Basic straight-dough bread-baking method – long fermentation
10-10B	Optimized straight-dough bread-baking method
10-11	Baking quality of bread flour – sponge-dough, pound-loaf method
10-13	Guidelines for testing a variety of products
10-15	Baking quality of angel-cake flour
10-31B	Baking quality of biscuit flour
10-50D	Baking quality of cookie flour
10-52	Baking quality of cookie flour – micro-method
10-53	Baking quality of cookie flour – macro-wire-cut formulation
10-54	Baking quality of cookie flour – micro-wire-cut formulation
10-90	Baking quality of cake flour
10-91	Use of layer cake measuring template
11 Biotechnology	
11-10	*Bt* cry1Ab-Modified corn in corn flour – ELISA method
11-20	StarLink corn in corn flour and corn meal – ELISA method
11-21	ELISA method for StarLink corn in corn flour and corn meal
12 Carbon dioxide	
12-10	Residual carbon dioxide in baking powder
12-20	Total (gasometric) carbon dioxide in baking powder
12-21	Total carbon dioxide in prepared mixes and self-rising flours
12-29	Table: correction factors for gasometric determination of carbon dioxide
14 Color and pigments	
14-10	Pekar color test (slick test)
14-22	Color of pasta – reflectance colorimeter method
14-30	Agtron color test for flour
14-50	Determination of pigments
20 Ingredients	
20-01	Egg solids – digitonin cholesterol method
20-10	Egg solids in pasta products
20-20	Determination of isoflavones in soy and selected foods containing soy by extraction, saponification, and liquid chromatography
22 Enzymes	
22-02	Measurement of α-amylase in plant and microbial materials using the ceralpha method
22-05	Measurement of α-amylase in cereal grains and flours – amylazyme method
22-08	Measurement of α-amylase activity with the Rapid Visco Analyzer
22-10	Measurement of α-amylase activity with the amylograph
22-11	Measurement of gassing power by the pressuremeter method
22-12	Measurement of α-amylase activity in flour supplemented with fungal α-amylase – modified amylograph method
22-14	Measurement of gassing power by volumetric method
22-15	Measurement of diastatic activity of flour or semolina
22-40	Measurement of trypsin inhibitor activity of soy products – spectrophotometric method
22-62	Measurement of proteolytic activity – spectrophotometric method
22-80	Qualitative test for peroxidase in oat products
22-90	Measurement of urease activity

Table 2 Continued

26 Experimental milling	
26-10A	Experimental milling: introduction, equipment, sample preparation, and tempering
26-21A	Experimental milling – Bühler method for hard wheat
26-22	Experimental milling – batch method for hard wheat
26-30A	Experimental milling – Bühler method for soft wheat short-extraction flour
26-31	Experimental milling – Bühler method for soft wheat straight-grade flour
26-32	Experimental milling – batch method for soft wheat
26-41	Experimental milling – Bühler method for durum wheat
26-42	Experimental milling – batch method for durum wheat
26-50	Brabender quadrumat Jr. (quadruplex) method
26-95	Experimental milling: temper table
28 Extraneous matter	
28-01	Apparatus or materials for extraneous matter methods
28-02	Reagents for extraneous matter methods
28-03	A special technique for extraneous matter methods
28-06	Cinder and sand particles in Farina – counting method
28-07	Cinder and sand particles in Farina – gravimetric method
28-10A	Macroscopic examination of external contamination in whole grains
28-19	External filth and internal insect infestation in whole corn
28-20A	Microscopic examination of external contamination in whole grains
28-21A	X-ray examination for internal insect infestation
28-22A	Cracking-flotation test for internal insects in whole grains
28-30A	Macroscopic examination of materials hard to hydrate
28-31A	Pancreatin sieving method, for insect and rodent filth in materials hard to hydrate
28-32A	Sieving method, for materials hard to hydrate
28-33A	Pancreatin nonsieving method for insect and rodent filth in materials easy to hydrate
28-40	Acid hydrolysis method for insect fragments and rodent hairs – wheat–soy blend
28-41B	Acid hydrolysis method for extracting insect fragments and rodent hairs – light filth in white flour
28-43	Glass plate method, for insect excreta
28-44	Iodine method, for insect eggs in flour
28-50	Decantation method, for rodent excreta
28-51A	Flotation method, for insect and rodent filth
28-60A	Tween-Versene method, for insect fragments and rodent hairs in rye flour
28-70	Defatting–Digestion method, for insect fragments and rodent hairs
28-75A	Sieving method, for light filth in starch
28-80	Flotation method, for insect and rodent filth in popped popcorn
28-85	Ultraviolet light examination, for rodent urine
28-86	Xanthydrol test, for urea
28-87	Urease-Bromthymol blue test paper, for urea
28-93	Direction of insect penetration into food packaging
28-95	Insect, rodent hair, and radiographic illustrations
30 Crude fat	
30-10	Crude fat in flour, bread, and baked cereal products not containing fruit
30-12A	Crude fat in cocoa
30-14	Crude fat in baked pet food
30-16	Crude fat in dry milk products
30-18	Crude fat in egg yolk by acid hydrolysis
30-20	Crude fat in grain and stock feeds
30-25	Crude fat in wheat, corn, and soy flour, feeds, and mixed feeds
30-40	Unsaponifiable matter
32 Fiber	
32-05	Total dietary fiber
32-06	Total dietary fiber – rapid gravimetric method
32-07	Soluble, insoluble, and total dietary fiber in foods and food products
32-10	Crude fiber in flours, feeds, and feedstuffs
32-20	Insoluble dietary fiber
32-21	Insoluble and soluble dietary fiber in oat products – enzymatic–gravimetric method
32-22	β-Glucan in oat fractions and unsweetened oat cereals
32-23	β-Glucan content of barley and oats – rapid enzymatic procedure
32-25	Total dietary fiber – determined as neutral sugar residues, uronic acid residues, and Klason lignin (Uppsala method)
32-28	Polydextrose in foods by ion chromatography
32-31	Fructans in foods and food products – ion-exchange chromatographic method

Table 2 Continued

32-32	Measurement of total fructan in foods by an enzymatic/spectrophotometric method
32-33	Determination of *trans*-galactooligosaccharides in selected food products by ion-exchange chromatographic method
33 Sensory analysis	
33-50A	Sensory evaluation – triangle difference test
38 Gluten	
38-10	Gluten – hand washing method
38-12A	Wet gluten, dry gluten, water-binding capacity, and gluten index
38-20	Farinograph test for vital wheat gluten
39 Infrared analysis	
39-00	Near-infrared methods – guidelines for model development and maintenance
39-10	Near-infrared reflectance method for protein determination in small grains
39-11	Near-infrared reflectance method for protein determination in wheat flour
39-20	Near-infrared reflectance method for protein and oil determination in soybeans
39-21	Near-infrared reflectance method for whole-grain analysis in soybeans
39-25	Near-infrared reflectance method for protein content in whole-grain wheat
39-70A	Near-infrared reflectance method for hardness determination in wheat
40 Inorganic constituents	
40-10	Aluminum – qualitative method
40-15	Ammonia – quantitative method
40-16	Ammonium salts – qualitative method
40-18	Ammonium salts – quantitative method
40-20	Calcium in bread and flour
40-21	Calcium in feedstuffs
40-26	Calcium in mineral feeds
40-30	Chlorides in ash as sodium chloride – gravimetric method
40-31	Chlorides in ash as sodium chloride – volumetric method
40-33	Chlorides in yeast foods – quantitative method
40-35	Iodine determination
40-40	Iron – qualitative method
40-41B	Iron – spectrophotometric method
40-45	Acid-soluble manganese
40-50A	Sample preparation for phosphate determination in flour improvers
40-56	Phosphorus – modified Fiske–Subbarow colorimetric method
40-57	Phosphorus – gravimetric method
40-58	Phosphorus – volumetric method
40-61A	Salt, calculated from soluble chlorides
40-66	Sulfates – gravimetric method
40-70	Elements by atomic absorption spectrophotometry
40-71	Sodium and potassium by atomic absorption spectrophotometry
40-75	Determination of minerals by inductively coupled plasma spectroscopy
42 Microorganisms	
42-10	Microorganisms – sampling procedure
42-11	Aerobic plate count
42-15	Coliform – *E. coli*
42-17A	*Clostridium perfringens* enumeration
42-20	Rope spore count
42-25B	*Salmonella* bacteria
42-30B	Enumeration of *Staphylococcus aureus*
42-35	Enterococci
42-40	Thermophilic spore counts (total aerobic, flat-sour, H_2S, non-H_2S anaerobic)
42-45	Thermophilic and psychrotrophic bacteria
42-50	Mold and yeasts counts
42-56	Ergot – ether-bicarbonate method
42-70	Smut – microscopic method
42-71	Smut – sedimentation method
44 Moisture	
44-01	Calculation of percent moisture
44-11	Moisture – dielectric meter method
44-15A	Moisture – air-oven methods
44-16	Moisture – air-oven (aluminum-plate) method
44-19	Moisture – air-oven method, drying at 135°
44-20	Moisture – ASBC air-oven method

Table 2 Continued

44-30	Moisture and volatile matter in fats and shortenings
44-31	Moisture and volatile matter in soy flours
44-40	Moisture – modified vacuum-oven method
44-51	Moisture – by distillation with toluene, for fats and shortenings
44-60	Moisture – drying on quartz sand
45 Mycotoxins	
45-01	Sampling grain for mycotoxins
45-05	Aflatoxin – thin-layer chromatography method
45-14	Aflatoxin – rapid screening method
45-15	Aflatoxin – presumptive test
45-16	Aflatoxin – liquid chromatography method
45-20	Zearalenone – thin-layer chromatography method
45-21	Zearalenone and α-zearalenol in corn – HPLC method
45-25	Identification of aflatoxin on TLC plates
45-41	Deoxynivalenol in wheat – TLC method
45-51	Fumonisins B_1, B_2, and B_3 in corn – liquid chromatography method
46 Nitrogen	
46-09	Crude protein – automated colorimetric method
46-10	Crude protein – improved Kjeldahl method
46-11A	Crude protein – improved Kjeldahl method, copper catalyst modification
46-12	Crude Protein – Kjeldahl method, boric acid modification
46-13	Crude Protein – Micro-Kjeldahl method
46-14B	Crude Protein – Udy dye method
46-15	Crude Protein – 5 min biuret method for wheat and other grains
46-16	Crude Protein – improved Kjeldahl method, copper–titanium dioxide catalyst modification
46-18	Crude Protein, calculated from percentage of total nitrogen, in feeds and feedstuffs
46-19	Crude Protein, calculated from percentage of total nitrogen, in wheat and flour
46-23	Nitrogen solubility index
46-24	Protein dispersibility index
46-30	Crude protein – combustion method
46-50	Urea and ammoniacal nitrogen
48 Oxidizing, bleaching, and maturing agents	
48-08	Benzoyl peroxide – quantitative method
48-42	Quantitative method for bromates
48-62	Ammonium persulfate – quantitative method
48-71A	Azodicarbonamide in premix
54 Physical dough tests	
54-10	Extensigraph method, general
54-21	Farinograph method for flour
54-28A	Farinograph table for constant dough weight method only
54-29	Approximate corrections for changing as-is farinograph absorption to 14.0% moisture basis, for constant dough weight method only
54-30A	Alveograph method for soft and hard wheat flour
54-40A	Mixograph method
54-50	Determination of the water absorption capacity of flours and of physical properties of wheat flour doughs, using the consistograph
55 Physical tests	
55-10	Test weight per bushel
55-20	Corn breakage susceptibility
55-30	Particle size index for wheat hardness
55-31	Single-kernel characterization system for wheat kernel texture
55-40	Particle size of wheat flour by laser instrument
55-50	Specific volume
55-99	Glossary – barley
56 Physicochemical tests	
56-10	Alkaline water retention capacity
56-11	Solvent retention capacity profile
56-20	Hydration capacity of pregelatinized cereal products
56-21	Flour swelling volume
56-30	Water hydration capacity of protein materials
56-40	Water hydration (absorption) of rolled oats
56-50	Pelshenke test (wheat-meal fermentation time test)

Table 2 Continued

56-60	Sedimentation test for flour
56-61A	Sedimentation test for wheat
56-62	Modified sedimentation test for wheat
56-63	Micro-sedimentation test for wheat
56-70	Sodium dodecyl sulfate sedimentation test for durum wheat
56-81B	Determination of falling number
56-99	Glossary – grain and flour
58 Special properties of fats, oils, and shortenings	
58-10	Cloud point
58-11	Cold test
58-12	Determination of oil color
58-13	Determination of congeal point
58-14	Consistency – penetration method
58-15	Determination of free fatty acids
58-16	Determination of peroxide value – acetic acid–chloroform method
58-17	Preparation of methyl esters of long-chain fatty acids
58-18	Fatty acid composition by gas chromatography
58-19	Total, saturated, unsaturated, and monounsaturated fats in cereal products by acid hydrolysis and capillary gas chromatography
58-20A	Refractive index
58-25	Solid fat index – dilatometric method
58-30A	Iodine value of fats and oils – cyclohexane – acetic acid method
58-35	Acetone-insoluble lecithin
58-39	Dropping point – automatic determination of melting point in fats
58-40	Melting point – capillary method
58-45	Monoglycerides and free glycerol
58-50	Saponification value
58-53	Slip melting point
58-54A	Oil stability index
58-82	Smoke, flash, and fire points
58-99	Glossary – lipids
61 Rice	
61-01	Amylograph method for milled rice
61-02	Determination of the pasting properties of rice with the Rapid Visco Analyzer
61-03	Amylose content of milled rice
61-99	Glossary – rice
62 Preparation of sample	
62-05	Preparation of sample: bread
62-20A	Preparation of sample: semolina and feedstuffs
62-25	Preparation of sample: fruit and fruit products
62-40	Preparation of sample: dried pasta and noodle products
62-50	Preparation of sample: malt
64 Sampling	
64-40	Sampling of fats and shortenings
64-50	Sampling of feeds and feedstuffs
64-60	Sampling of flour, grain products, and feed products in sacks
64-70A	Manual sampling of wheat and other whole grains
64-71	Mechanical sampling of dry, free-flowing granular material
66 Semolina, pasta, and noodle quality	
66-20	Determination of granularity of semolina and farina: sieving method
66-41	Macro-scale pasta processing
66-42	Micro-scale pasta processing
66-50	Pasta and noodle cooking quality – firmness
70 Solutions	
70-15	Preparation of buffer solutions
70-20A	Preparation and standardization of hydrochloric acid solution
70-25	Preparation of indicator solutions
70-40	Preparation and standardization of ammonium and potassium thiocyanate solutions
70-50A	Preparation and standardization of potassium permanganate solution
70-60	Preparation and standardization of silver nitrate solution
70-70	Preparation and standardization of sodium or potassium hydroxide solution

Table 2 Continued

70-75	Preparation and standardization of sodium thiosulfate solution
70-80	Preparation and standardization of sulfuric acid solution
74 Staleness/texture	
74-09	Measurement of bread firmness by universal testing machine
74-10A	Measurement of bread firmness – compression test
74-30	Staleness of bread – sensory perception test
76 Starch	
76-11	Starch – glucoamylase method with subsequent measurement of glucose with glucose oxidase
76-13	Total starch assay procedure (megazyme amyloglucosidase/α-amylase method)
76-21	General pasting method for wheat or rye flour of starch using the Rapid Visco Analyzer
76-30A	Determination of damaged starch
76-31	Determination of damaged starch – spectrophotometric method
78 Statistical principles	
78-40	Definitions of statistical terms
78-60	Statistical evaluation of test methods – estimation of variance in analytical tests
80 Sugars	
80-04	Determination of simple sugars in cereal products – HPLC method
80-05	Determination of saccharides by liquid chromatography
80-10	Determination of glucose in sugar mixtures – glucose oxidase method
80-50	Determination of sucrose
80-51	Solids in syrups – refractometer method
80-53	Solids in syrups – spindle method
80-60	Determination of reducing and nonreducing sugars
80-68	Determination of reducing sugars – Schoorl method
82 Tables	
82-20	Notes on use of tables 82-21, 82-22, 82-23, and 82-24
82-21	Table: conversion of farinograph absorption to 14.0% moisture basis (constant weight method only)
82-22	Table: correction of analytical values to 14.0% moisture basis
82-23	Table: flour weight to give 100 g at 14.0% moisture content
82-24	Table: multiplication factors to correct weights to 14.0% moisture basis
86 Vitamins	
86-01A	Vitamin A – ultraviolet absorption method
86-02	Vitamin A – Carr–Price method
86-03	Vitamin A in enriched flour
86-05	Vitamin A and carotene
86-06	Analysis of vitamins A and E by high-performance liquid chromatography
86-10	Ascorbic acid – indophenol–xylene extraction method
86-31	Vitamin B_6 complex – microbiological method
86-40	Vitamin B_{12} – microbiological method
86-45	Choline
86-47	Total folate in cereal products – microbiological assay using trienzyme extraction
86-49	Niacin in enrichment concentrates
86-50A	Niacin and niacinamide in cereal products
86-51	Niacin – microbiological method
86-70	Riboflavin – fluorometric method
86-72	Riboflavin – microbiological method
86-80	Thiamine – thiochrome method
86-90	B-vitamins in vitamin concentrates by HPLC
89 Yeast	
89-01	Yeast activity, gas production

Reproduced with permission from AACC website.

of samples whose composition has been determined by the basic methods of oven drying for moisture (AACC method group 44 and ICC method 109), elemental analysis of nitrogen content for protein (ICC method 167 and AACC method group 46), and solvent extraction for oil and fat (ICC method 136, AACC method group 30).

These methods have also been adapted to analyses of milled and baked products. For flour and food products, a wider range of compositional analyses may be required, including the content of starch (AACC method group 76, ICC methods 122, 123, and 128), nonstarch polysaccharides and fiber of various types (ICC methods 113, 140, and 156; AACC

method group 32), specific types of lipids (fats and oils) (AACC method group 58), vitamins (ICC methods 111, 112, 117, and 119; AACC method group 86), and heavy metals (ICC methods 141 and 154).

Simulation of Grain Processing

Many of the methods of analysis are designed to predict how a consignment of grain or flour will perform in processing. Most obvious are methods that are small-scale versions of the real process. For example, equipment and procedures have been developed for laboratory-scale milling (AACC method group 26). Following milling (laboratory- or full-scale), a common method to determine the quality of the resulting flour is to assay the flour for its ash content (AACC method group 08, ICC methods 104 and 157), i.e., the mineral residue remaining after burning off the combustible materials, such as protein, fat, and starch.

Likewise, small-scale versions are available for the analysis of wheat to mimic the processes of making bread, pasta, noodles, and other food products (*see* **Cereals**: Overview). Predictive of these product-related methods are the significant aspects of flour performance that influence processing, especially dough properties (ICC methods 114, 115, 121, and 126; AACC methods group 10). Further groups of methods determine specific aspects of composition that are known to provide a correlation to performance in the real process. These include gluten strength (ICC methods 155 and 158; AACC method group 38) and sedimentation tests (AACC methods 56-60 to 56-63 and 56-70; ICC methods 116, 118, and 151).

Methods for Food Processing

Further methods describe the means of testing the quality of a range of ingredients that may be used in the preparation of grain-based foods (AACC method groups 20 and 58). Other methods relate to the evaluation of finished products according to their color (AACC method group 14) and their taste and mouth feel (sensory analysis, AACC method 33-50). Paramount for food production is the need to test for food safety, i.e., the need for assurance of the absence of pathogenic microorganisms (ICC methods 125, 133, 134, 139, 144, 147, and 206; AACC method group 42).

Methods for the Diversity of Grains

The main accent in the AACC and ICC standard methods is on wheat and wheat-based foods, but there are also analyses of product and processing quality for rice; these mainly involve the quality of rice starch (AACC method group 61). Methods for barley testing are provided by the European Brewing Commission (EBC).

Oilseed Methods

Greater accent on fats and oils is provided by standard methods of the American Oil Chemists' Society (AOCS). These are available as a loose-leaf manual of 1200 pages or online at the AOAC website. Their methods include sections on vegetable-oil source materials (section A), oilseed by-products (section B), commercial fats and oils (section C), and various other methods for the wider range of fats, oils, and surfactants. Specific methods of relevance to oilseed analysis include, e.g.,

- determination of oil content in oilseeds,
- oil content of oilseeds by nuclear magnetic resonance,
- oil in oilseeds: supercritical fluid extraction method,
- determination of oil, moisture and volatile matter, and protein by NIR reflectance, and
- total hexane content in extracted meals.

Plant Breeding

Many of these testing methods are also essential to the needs of plant breeders, who must evaluate the suitability for specific end uses of the many cross-bred lines coming through their breeding programs, whatever the grain species (*see* **Canola**: Genetics and Breeding. **Maize**: Breeding. **Rice**: Breeding. **Soybean**: Germplasm, Breeding, and Genetics. **Wheat**: Breeding). In the late stages of breeding, there may be $\sim$1 kg of grain for advanced lines, sufficient for test milling and test baking if, for example, the aim were to produce a bread wheat. At earlier stages of breeding, the amount of grain is much less, and very small scale methods have been devised to suit these specific purposes, so that lines that perform poorly for end-use quality can be eliminated from the breeding program, thereby avoiding the unnecessary propagation of poor lines.

Conclusion

Suitable methods of analysis are essential to the ongoing development of the grain-processing industries, both internationally and locally. These methods permit the comparison of test results between laboratories and between countries. Without this ability, it would be impossible to establish codes for the hygiene and composition of grains and of foods made from them. New methods are now taking advantage of the biotechnology era, as well as addressing the

challenges of biotechnology. For example, AACC methods in the biotechnology group (11) provide the means of determining the presence of genetically modified corn (*see* **Genetically Modified Grains and the Consumer**), using methods from the new biotechnology, namely, immunological assays. These parallel trends are likely to expand, with the increasing need to identify and segregate grains that have resulted from genetic modification. On the other hand, molecular biology is delivering a wide range of efficient testing methods, whereby analysis can be conducted by targeting the presence or absence of specific marker genes or marker proteins (*see* **Variety Identification of Cereal Grains**).

APPENDIX 5

Units of Grain Science

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

Until the whole world shares one common "language" for units of measurement, there will be a need for conversion tables, such as are provided in this appendix. There is a bewildering array of units, many of them are no longer in common use; examples include tons and tonnes, fathoms and furlongs, pennyweights and hundredweights, stones and scruples, gills and grains, drams and pecks, poles and perches, rods and roods, and leagues and bags. An ounce is a different measure depending on whether it is a dry or liquid measure, and depending on whether it is an ounce Troy, an Apothecaries' ounce or an ounce Avoirdupois! Agreement on units of measurement is no less important today for grain science, in the many disciplines that make their contributions, than such agreement has been through the ages.

Throughout this encyclopedia, the standard is to quote units as metric, and indeed this is usual throughout the scientific community worldwide. However, it is appropriate that there should be the provision of conversion tables between metric and US units in this appendix, because the metric system of units is still not in common use in some English-speaking countries. This is especially so for the USA, although the USA is officially on the metric system. All US units are defined in terms of the SI system of metric units *(Systeme Internationale d'Unites)*.

The use of customary US units continues to be permitted in trade, but they are not mandated. In many cases, including consumer foods, e.g., canned foods and packaged baking mixes, they are dual-labeled in US customary units and in their metric equivalent. In medicine, metric units are used almost exclusively. Metric units are also used for some alcoholic beverages. The provision of conversion tables is also needed for many of the current and older generations in countries that have adopted the metric system relatively recently, as they may still think in imperial terms for infrequently used units.

Added problems for the use of units of measurement relate to the lack of standardization of units in nonmetric systems. Many of the British imperial units are differently defined in the USA. Some of these problems are discussed and explained in the text below. However, the table of conversions below is confined to conversion between the US system and metric units.

In addition, explanation is needed for a range of nonstandard units used in some branches of grain science. Such instances are discussed in this appendix, thereby providing a focus for this information, which is also spread throughout the encyclopedia.

Historical Perspective – The Metric System

Agreement on units of measurement has been necessary since the beginnings of civilization. For example, it was all very well for the cubit to be used to measure short lengths, based on the distance from the elbow to the fingertip, but when accuracy mattered, whose elbow and whose fingertip? According to the Oxford dictionary, this measurement ranged from 18 to 22 inches. So, presumably, the matter of standardization was resolved by decree: the standard elbow and fingertip would be the king's arm!

Anatomical origins obviously also apply to the foot, still in limited use officially, but discontinued in France following the French Revolution of 1789. Prior to that date, the familiar unit was the *pied-de-roi* (king's foot), similar, but not identical, to the British foot. However, even within France, the *pied-de-roi* varied from province to province. The foot of Paris was 11% longer than that in Strasbourg, but 10% shorter than the foot measure in Bordeaux. Such impediments to trade were addressed by the French scientific community following the French Revolution. The French *Academie des Sciences* was given the responsibility of producing a unified system of weights and measures by act of Parliament in 1790.

Although France and England were officially at war at the time, the decree of 1790 stated that the King of England should be approached for England to join in the process of standardizing the system of weights and measures. It is still unclear whether this invitation was ever relayed to the English or, if it was, what response was provided. If Anglo-French cooperation had proceeded at that time, we would probably be a more unified world a few centuries later, in view of the subsequent spread of the British imperial system.

Furthermore, the basis of the unit of length might also be much simpler, because a pendulum system was proposed for the joint action with the Royal Society of Britain. According to this system, the basic measure was the length of a pendulum with a period of one second (as familiar as the grandfather clock) giving a system of kilopendules, millipendules, and cubic pendules.

Instead, however, the *Academie des Sciences* settled for the meter as one ten-millionth part of one-quarter of the Earth's meridian. Initially, this was to be based on accurate measurement of the distance from Dunkirk to Barcelona. The interim project, begun in 1793, involved measurement only to Collioure in the south of France. This measure has stood the test of time much better than others in the original package, such as a 10 h clock, a circle divided into 400 grades (still finding some use), and a Republican calendar, starting on September 22nd (the autumnal equinox in the northern hemisphere) with 12 months, each divided into three 10 day periods, plus a 5 day holiday period (or 6 day holiday period in a leap year).

Imperial Units – The British and US Versions

Following the transfer of the British imperial system of weights and measures to the USA a few centuries ago, separate evolution has occurred on either side of the Atlantic ocean, introducing further inconsistencies between the two versions of what is known as the imperial system of Units. The differences include the following examples:

- the US gallon (3.785 l) is smaller than the British gallon (4.546 l);
- the US "short" ton of 2000 pounds (907.2 kg) is shorter measure than the British "long" ton of 2400 pounds (1016 kg), made up of 20 hundredweight (cwt) of 112 pounds each;
- the US bushel (35.24 l) consists of 32 dry quarts, or 8 US gallons, or 4 pecks. It differs from the British "Winchester" bushel (8 British gallons), which is 36.37 l.
- the British "bag" of 3 bushels (0.109 m^3) is not in general use in the USA, but it is a farmers' unit in former British colonies such as Australia.
- the US hundredweight (cwt) (45.36 kg) is 100 pounds (as the name suggests), significantly less than the British hundredweight of 112 pounds (50.80 kg). One story to explain this anomaly refers to the shipping of wool from Australia to Britain in the nineteenth century. Bales of wool started as 100 pounds on the dry Australian sheep station, but they gained moisture during the long ocean voyage in the wool clippers to become 112 pounds on arrival in Britain.

To the extent that metric units have been used in USA, there have been differences in spelling to further confound the possibility of standardization. For example, the tonne, litre, metre and gramme of the SI metric system are the metric ton, the liter, the meter and the gram in US use, respectively. Potentially, international adoption of the SI metric system is a unifying principle to overcome these anomalies, but habitual use of traditional systems dies hard. On the assumption that the use of nonmetric units is more prevalent in the US than elsewhere, the table of conversions to metric units (Table 1) relates primarily to US units, using US spelling for the metric units.

The International System (SI) of Units

The SI system of units is the modern version of the metric system. The General Conferences on Weights and Measures (1954–71) agreed on seven base units for seven basic quantities as the foundation of the SI system. These are:

- the meter (m) for length;
- the kilogram (kg) for mass;
- the second (s) for time;
- the ampere (A) for electric current intensity;
- the kelvin (K) for thermodynamic temperature;
- the mole (mol) for amount of substance; and
- the candela (cd) for luminous intensity.

A much longer set of derived SI units was based on these. The basic SI units for area and volume are thus obtained by raising the unit for length to the second and third powers, respectively. A more complex case is the set of derived units for energy, which may be expressed as the meter squared kilogram per second squared ($m^2\,kg\,s^{-2}$), also called the joule (J), the newton meter (N m), and the volt ampere second (V A s). These three terms for energy are equivalent; the user may choose which is appropriate to use in a specific context.

General Conferences on Weights and Measures (1960–75) adopted a set of decimal multiples as SI prefixes. The more common ones are:

- giga (G) for 10^9,
- mega (M) for 10^6,
- kilo (k) for 10^3,
- hecto (h) for 10^2,
- deci (d) for 10^{-1},
- centi (c) for 10^{-2},
- milli (m) for 10^{-3},
- micro (μ) for 10^{-6}, and
- nano (n) for 10^{-9}.

Table 1 Conversion between metric units (mostly SI units) and US units

Metric units	*US units*
Length	
1 centimeter (cm)	0.3937 inch (in)
25.4 millimeter (mm)	1 in
1 meter (m)	3.2808 feet (ft)
0.3048 m	1 ft
1 m	1.094 yard (yd)
0.9144 m	1 yd
1 kilometer (km)	0.6213 mile
1.6093 km	1 mile
Area	
1 square centimeter (cm^2)	0.1550 square inch (in^2)
645.2 square millimeters	1 in^2
1 square meter (m^2)	10.76 square feet
1 m^2	1.196 square yard
1 m^2	0.0002471 acre (ac)
1 hectare (ha)	2.471 acres
0.4047 ha	1 acre
1 ha	0.00386 square mile
259.0 ha	1 square mile (1 "section")
Volume	
1 cubic centimeter (cc)	0.0610 cubic inch
16.38 cc	1 cubic inch
1 milliliter (ml)	0.3382 fluid ounce
29.57 ml	1 fluid ounce
1 liter (l)	0.2642 US gallon
3.785 l	1 US gallon
1 hectoliter (hl)	26.42 US gallons
1 hl	2.838 US bushels
35.24 l	1 US bushel
1 l	0.02838 US bushel
0.9463 l	1 quart (liquid)
Mass	
1 gram (g)	0.0353 ounce
28.35 g	1 ounce
1 kilogram (kg)	2.205 pounds (lb)
0.4536 kg	1 lb
1 quintal (q) (100 kg)	220.5 lb
45.36 kg	1 US hundredweight (cwt) (100 lb)
1 tonne (t) (metric ton)	1.102 US short ton (2000 lb)
0.9072 t	1 US short ton
1 t	0.9843 US long ton (2205 lb)
1.016 t	1 US long ton
Grain yield	
1 q ha^{-1}	0.79 cwt/acre
0.1235 tonne/ hectare (t ha^{-1})	1 bag/acre
1 t ha^{-1}	14.86 bushels/acre for wheat
6.73 t ha^{-1}	100 bushels/acre for wheat
1 t ha^{-1}	13.87 bushels/acre for maize
1 t ha^{-1}	11.89 bushels/acre for barley
Bulk density	
1 kilogram/ hectoliter (kg hl^{-1})	0.7770 pound/US bushel
1.287 kg hl^{-1}	1 pound/bushel
Power	
1 kilowatt (kW)	1.341 horsepower (hp)
0.7457 kW	1 hp
Energy	
1 joule (J)	0.239 calorie (cal)
4.187 J	1 cal
1 kilojoule (kJ)	0.945 British thermal unit (BTU)
1.055 kJ	1 BTU
Temperature	
0°C (celsius)	32°F (fahrenheit)
20°C	68°F (about "room temperature")
100°C	212°F
Pressure	
100 pascals (Pa)	1 millibar (mbar)
Dynamic viscosity	
1 pascal second	1 poise

Standard Measures in Grain Science

Units of Grain Harvesting

In science generally, and in grain science specifically, the SI system of metric units is happily accepted. Yet, at harvest, farmers might still measure their grain yields in "bushels per acre," or even in "bags to the acre," with grain volume given in US bushels, Winchester bushels, hectoliters, or in quintals.

In "dry measure" of volume, the US bushel is 2150 cubic inches or 8 gallons or 4 pecks or 32 dry quarts. One dry quart equals 67.20 cubic inches or 1.101 l. In the metric system, grain yield is measured in tonnes per hectare (t ha^{-1}), i.e., units of mass per unit of area. However, the US tradition has been to measure yield in bushels per acre, i.e., units of volume (not mass) per unit of area. The use of volume measurement units for grain in the US makes it difficult to provide direct conversion between metric and US units for grain yield. To overcome this problem, the US government has defined the bushel for grains in commerce in terms of weight, irrespective of the true test weight. Standard volume–mass values for the various cereals are:

- 1 bushel of wheat = 60 pounds;
- 1 bushel of maize = 56 pounds;
- 1 bushel of oats = 32 pounds;
- 1 bushel of barley = 48 pounds; and
- 1 bushel of rye = 56 pounds.

Thus, it is possible to convert grain yields, depending on the grain being considered. When the grain in question is wheat, 100 bushels per acre is 6000 pounds per acre equal to 2723 kg for 0.4047 ha, or 6.73 t ha^{-1}. A rough "rule-of-thumb" is to take the yield of wheat in pounds per acre and increase it by 10% to get kg ha^{-1}. Correspondingly, 1 t ha^{-1} equates to 14.86 bushels per acre for wheat, 13.87 bushels per acre for

maize, 7.92 bushels per acre for oats, 11.89 bushels per acre for barley, and 13.87 bushels per acre for rye.

With the British "bag" measuring 3 bushels, $1\,t\,ha^{-1}$ (~15 bushels per acre) approximates to five bags to the acre – a farmer's on-the-spot measure of wheat yield.

Units for Temperature

Temperature is another case of difficulties for conversion, because the fahrenheit and celsius (centigrade) scales do not correspond at any reasonable temperature (they equate at −40°). Conversion between the scales involves taking into account the differences between the scales in the slope (ratio of 9:5) and the freezing point of water (0°C and 32°F). To convert a temperature from celsius to fahrenheit, multiply °C by 9, divide the result by 5, and add 32. To convert a temperature from fahrenheit to celsius, deduct 32 from the temperature in °F, multiply by 5, and divide by 9.

Cereal-Based Foods and Nutrition

Several articles and a major appendix in this encyclopedia relate to the food end of the grain production–utilization chain. It is thus necessary to explain units in this area, which eventually involves the home kitchen. These articles use units such as cups (CU), tablespoons (TB), teaspoons (tsp), and fluid ounces (FO). This last unit is defined in Table 1. Household units are more difficult to define. Their use in this encyclopedia is provided below.

These US measurements may use the same word for two measurements that are different. An ounce can be one-sixteenth of a pound (weight measure) or one-sixteenth of a pint (volume measure). A fluid ounce and an ounce of weight may be two different amounts, depending on the density of the ingredients being measured. In countries outside of the USA, cooks usually measure solid ingredients by weight. US measurements are based on fluid measures used for water or milk, and for dry ingredients such as flour and sugar, and for solid ingredients such as shortening. Commonly used equivalents are:

- 1 tablespoon (TB) = 3 teaspoons = 15 ml;
- 1 teaspoon (tsp) = $\frac{1}{3}$ tablespoon = 5 ml;
- 8 tablespoons = $\frac{1}{2}$ cup or 4 ounces or 1 teacup;
- 16 tablespoons = 1 cup; and
- 1 cup (CP) = $\frac{1}{2}$ pint or 8 fluid ounces = 237 ml.

The names of some British units have the same names as US measurements, but are not identical to US units. Overall, weights are equivalent but volumes differ. An English measuring cup (English breakfast cup) is ~32% larger than the US cup, measuring ~312 ml.

Chemistry Units

Standard chemical units are used throughout the encyclopedia. These include estimates of the amounts and sizes of molecules, especially macromolecules, such as proteins. The mole (abbreviated to mol) is described above as one of the seven basic units of the SI system, being (approximately) the amount of the substance expressed as its molecular mass in grams. The size of a molecule is given as its molecular mass in daltons (abbreviated to Da) or its relative molecular mass (M_r with no units). In both cases, the number indicates approximately the size of the molecule as a multiple of the size of the hydrogen atom, taken to be 1 Da. More correctly, however, the unit is taken to be one-twelfth of the mass of the carbon nuclide ^{12}C.

The Svedberg unit (S) is a less common unit used in relation to estimating the size of macromolecules. In particular, it is an estimate of the size of a protein molecule, based on how fast it sediments under the very large centrifugal force of the ultracentrifuge. This rate of sedimentation is measured in sedimentation units. One Svedberg unit equals 10^{-13} sedimentation units. The Svedberg unit is often used, for example, to characterize the proteins of the legume grains. Examples are vicilin and legumin, which are indicated to be 7S and 11S, respectively (*see* **Protein Chemistry of Dicotyledonous Grains**).

Units for Cereal Chemistry Testing

It is still normal practice for cereal chemists to measure the resistance to extension of a dough in Brabender units, and to determine the activity of α-amylase (the enzyme that hydrolyzes starch) in Farrand units or in stirring number units. Such nonstandard units may not be a problem to people working in the same topic area. They have worked during the development of these methods of analysis. In some cases, these units may be intentionally perpetuated, because a manufacturer or inventor sees the names for these units as a valuable means of advertising.

Although these units are meaningful and familiar for those who are using the test systems all the time, standard units would be more appropriate for the newcomer to the field. The adoption of standard units would also be conducive to international standardization of the method. This surely is the main reason for the use of SI units, namely, that they form a sound basis of universal understanding of what analytical results mean from one time to another and from one lab to another. In this encyclopedia,

there is therefore the need to explain the basis for the nonstandard units of grain science, as well as providing conversion tables for interchange between the metric and US Systems.

The Moisture Basis for Grain and Flour Data

Irrespective of what units are used, it is important to be aware of the moisture basis on which composition data are based for grain and flour samples. For example, protein content may be quoted in various forms, namely, on a dry-weight basis, on the basis of a specified moisture content (e.g., 14.5% moisture), or on an "as is" basis (the moisture content of the sample as it was at the time of testing). Figure 1 provides the means of converting values for protein content from a known moisture basis to either 11.0% or 13.5% moisture content.

Furthermore, when flour milling is under consideration, "extraction" terms may need to be clarified. For example, some mills base 100% extraction and mill capacity on the dry weight of wheat, whereas others base such estimates on the weight of wheat after the process of tempering, also known as conditioning, during which its moisture content is adjusted to a suitable level, often 14.5% moisture. Alternatively, mill capacity may be based on the production capacity for all flour products. A US flour mill making 78 000 pounds of flour from 100 000 pounds of wheat grain would be described as a 780 cwt mill in the US, but not in Europe.

Measurement Units of Dough Testing

Resistance Units and the Mixograph

When American scientists, Swanson and Working, developed the recording mixograph dough mixer in the early 1930s, the vertical axis of the mixograph trace was left unlabeled, providing no quantitative indication of the resistance of the dough to mixing. In their 29-page article, they described how an early

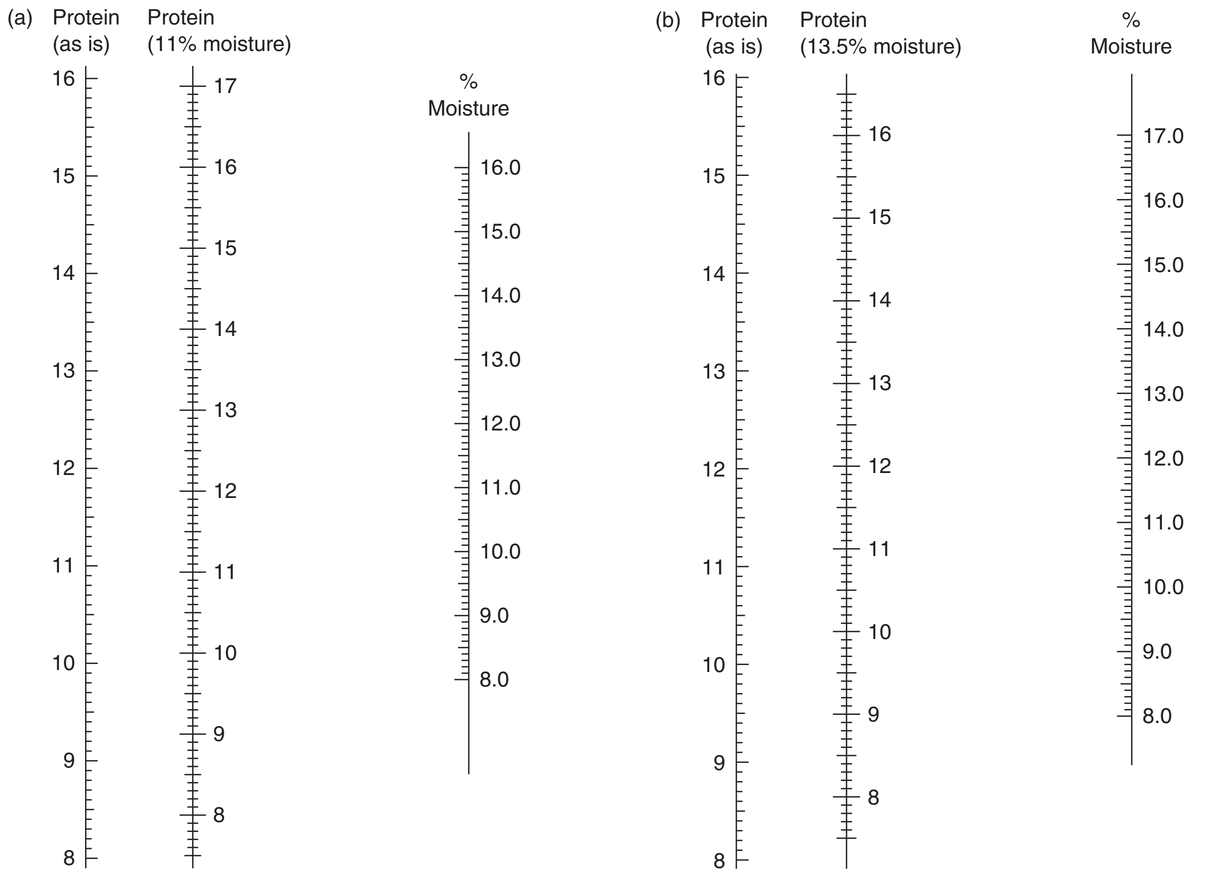

Figure 1 Conversion graph to permit the alteration of the protein content of a cereal-grain sample from a known moisture basis: (a) to an 11% moisture basis or (b) to a 13.5% moisture basis. To do so, a ruler is used to join the observed protein content of the sample on the left-hand scale to the moisture content of the sample (right-hand scale) is used. The point where the ruler crosses the inner scale is the protein content of the sample, based on either (a) 11% or (b) 13.5% moisture. (Adapted from the Cereal Chemistry Division Official Methods, Royal Australian Chemical Institute, Melbourne, Australia.)

version measured watts of electric power to the mixer, not dissimilar to the direct-drive mixograph, developed in the 1990s with electronic data collection. In the first reports of the latter, the vertical axis was again labeled as "arbitrary units," but subsequently procedures were developed to express the vertical (resistance) axis in grams of force for the conventional moving-bowl mixograph by attaching a pulley and calibration weights to the moving arm. This approach is valuable, but it can also be complicated by the design of some mixographs to measure dough samples of differing sizes; as a result, the scale can be simply labeled as "% of full scale."

Traditional and Newer Dough-Testing Equipment

The Brabender farinograph and extensigraph use a combination of SI units and "Brabender units" (BUs) in the testing of various aspects of dough testing. No standard units have become adopted for the BU, so it remains as a measure that is meaningful for cereal chemists, who regularly use the equipment, or for those who are involved in interpreting the results, e.g., wheat breeders.

Recently developed research instruments for emulating the dough-test processes of the Brabender farinograph and extensigraph with very small dough samples (a few grams) have been designed specifically for automatic data capture, to correlate with the results from more traditional instruments, and to provide results in SI units, namely, in grams (vertical axis of the mixing curve) and centimeters (horizontal axis).

Other recently developed dough-testing instruments are calibrated and read out in SI units. In the case of the doughLAB (Figure 2), an instrument similar to the Brabender farinograph, data are reported in either newton meters (N m), or farinograph units ("FU"). The relationship between these units is unfortunately not constant, but differs with the choice of bowl, namely, that for the 300 g bowl, 500 FU = 4.90 N m and for the 50 g bowl, 500 FU = 0.98 N m.

Measurement Units of Enzymic Activity and Starch Viscosity

The Falling Number Unit

One of the strange names for units in grain science is the "falling number unit," akin to the (also strange) stirring number unit. The falling number method was developed in Sweden in response to the need for a means of quantifying the degree of sprout damage to grain as a result of premature germination caused by rain at harvest. It provides a measure of the enzymic action of α-amylase on the endogenous starch for the germinating grain. It is applicable to several cereal species, especially wheat and rye. The results are provided as the number of seconds taken for a plunger to fall through a heated mixture of ground grain and water; a short falling time, e.g., 100 s, indicates extensive sprout damage. One falling number unit is thus simply equal to 1 s of falling time, but nevertheless the name falling number unit is still in common use in grain trading.

The Stirring Number Unit

The "stirring number method" was developed in 1984 and 1985 following widespread rain damage to the Australian wheat crop. Research was initiated to develop an instrument that could detect this damage, like the established falling number method, but would be robust and rapid, thus better suited to the harsh conditions of the Australian silo (grain-receival site). The instrument produced was called the Rapid Visco Analyzer (RVA), and a 3 min test was devised to detect sprout damage. The test works by using stirring action to mix and measure the viscosity of a slurry of wheatmeal and water as it is heated. Apparent viscosity is measured continuously as the power requirement of the stirring motor. The viscosity of rain-damaged samples is markedly lower than that of undamaged grain because of starch hydrolysis by the sprouting enzyme.

The stirring number unit (later renamed the "rapid visco unit") was chosen for routine output from the method to provide results in a range that would make the measurement easily accessible to farmers and grain traders. The range chosen was from near zero (poor-quality damaged grain) to ~150 (good-quality sound grain).

The Rapid Visco Unit and Centipoise

Nevertheless, at the outset of developing the RVA, the use of standard units of viscosity was seen as essential. Initially, the RVU was devised as a unit for the more general use of the RVA in characterizing starch properties. This unit of apparent viscosity can be related to international units through the relationship 1 RVU = 12 centipoise (cP). Traceable calibrations were then developed for the RVA, which now provides data in centipoise (1 centipoise = 1 millipascal second (an SI unit) abbreviated to mPa s).

Conclusion

While there may be general agreement that it is desirable to standardize units of measurement, the world is still far from uniform in this respect. There may be less general agreement that the SI/metric system is the only one by which standardization can be

(a)

(b)

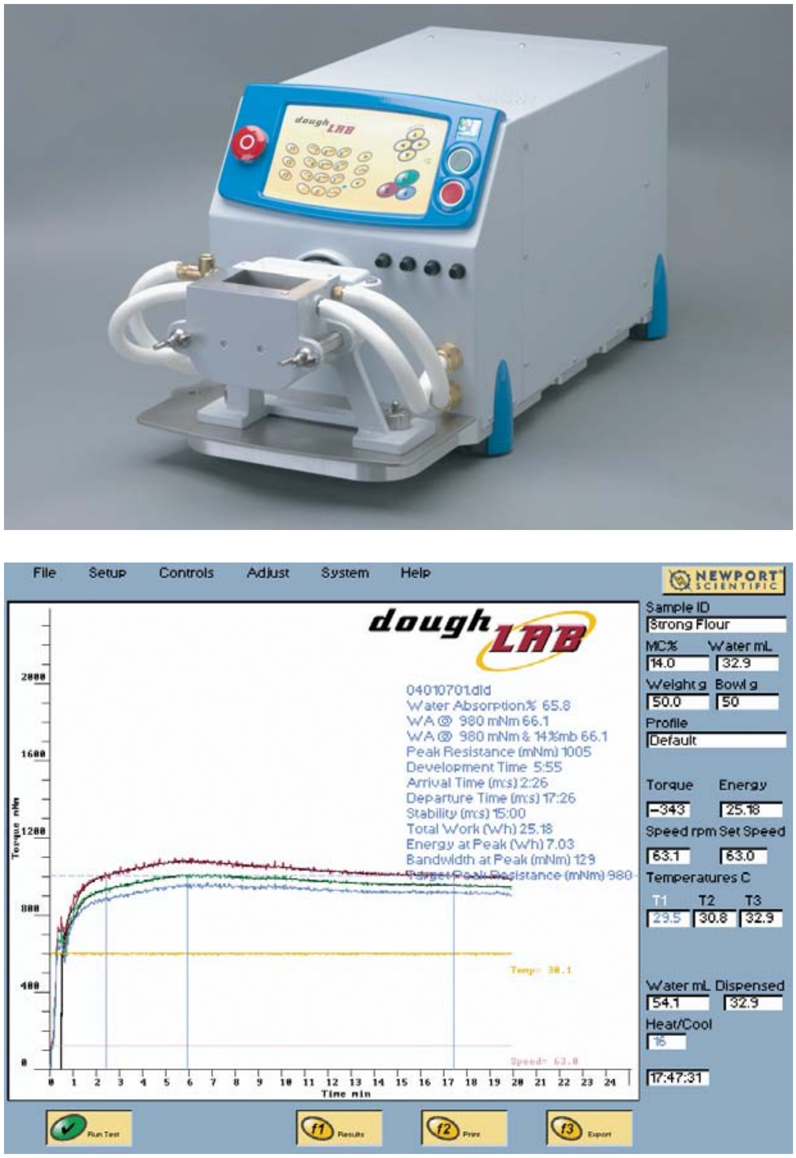

Figure 2 (a) The doughLAB equipment, designed to provide dough-test results in SI units (newton meters). Dough is mixed in the tiny chamber in front. (b) Mixing curve for a strong flour from the doughLAB, showing the vertical axis in millinewton meters. The mixing action produces a broad band of torque, whose width is indicated by the two outer traces. The inner trace shows the mean of the mixing curve. Resistance to mixing starts from zero and rises as the dough forms, reaching a maximum (for this sample) after mixing for ~6 min. Thereafter, the resistance to mixing decreases only slightly, showing that this dough would have a good tolerance to over-mixing in the bakery. A much greater decrease in "breakdown" after the peak would be indicative of a weak flour, which would also have a shorter time to the peak of mixing torque. (Illustrations provided by Newport Scientific, Sydney, Australia.)

achieved; there is no other real contender. Until international standardization is adopted in practice, it will be necessary to provide conversion tables, such as are given in Table 1. Nevertheless, the general agreement in the scientific community on SI units sets an example for the rest of the world, demonstrating the added efficiency of uniformity in units of measurement.
